Key Points:

- Observations of differences in mobility and grain-scale behaviour of the same granular material in dry and wet flows are rare
- Dry and saturated experimental flows conducted in a large laboratory flume for five source volumes of 0.2 to 1.0 m³.
- Distal reach of saturated flows showed clear scaling effects with source volume not observed in dry flows

Corresponding author: W. Andy Take, Andy.Take@queensu.ca

Abstract

The presence of a pore fluid is recognized to significantly increase the mobility of saturated over dry granular flows. However, experimental studies in which both the bulk-scale (runout) and grain-scale behaviour of identical granular material in a dry and saturated initial state are directly compared are rare. Further, the mechanisms through which pore fluid increases mobility may not be captured in experimental flows of small volume typical of laboratory conditions. Here we present the results of dry and initially fluid saturated or “wet” experimental flows in a large laboratory flume for five source volumes of 0.2 to 1.0 m³. Our results demonstrate that the striking differences in the nature of interactions at the particle scale between wet and dry flows can be directly linked to macro-scale behaviour: in particular, a greatly increased mobility for wet granular flows compared to dry, and a significant influence of scale as controlled by source volume. This dataset provides valuable test scenarios to explore the fundamental mechanisms through which the presence of a pore fluid increases flow mobility by first constraining the frictional properties of the material (dry experiments), permitting an independent evaluation of the implementation of interstitial fluid effects in numerical runout models (wet experiments).

Plain Language Summary

An accurate prediction of how fast and how far a landslide, such as a debris flow, will travel is essential to define the hazard posed to life and property by these geophysical flows. While dry frictional flows often behave according to the simple physics of friction resisting motion, water saturated granular flows tend to travel farther and faster than the same scenario under dry conditions. In this paper we explore this phenomenon in detail, using high-speed image analysis to look for and quantify differences in grain-scale behaviour that might lead to increased mobility in saturated over dry flows, and high definition laser scans to quantify how far the debris travelled. Large flume tests comparing dry versus saturated flows for five source volumes of 0.2 to 1.0 cubic metres reveal that, in contrast to dry flows, saturated flows travel significantly farther as the volume of the landslide increases. This data is unique as it will enable researchers to test how well numerical simulations are able to model the travel behaviour of the same material in a dry and water saturated state.

1 Introduction

The quantification of the hazard posed by a potential landslide source volume requires an accurate prediction of the travel path and distal reach of the debris. This is generally accomplished in practice by using runout observations from past landslide events in the same location or similar geologic materials to delineate potential hazard areas for future landslides. These observations are then used either within an empirical-statistical approach to define runout exceedance probability (Legros, 2002) or by inferring debris rheological models and parameters from numerical simulations to match runout and inundation depth trimlines of historical events (McDougall, 2017). Heim’s Ratio (H/L) was an early empirical-statistical proposal of a parameter for risk assessment by geometrical similarity (Figure 1). The total runout length L has the components of translation of the centre of mass L_{COM} and spreading of the material ahead of the centre-of-mass S_f (Dade & Huppert, 1998; Staron & Lajeunesse, 2009), while the difference in elevation, H , is measured from the back of the head scarp to the front of the debris. The total runout length L is typically of greatest interest for hazard assessment whereas the potential energy of the source volume is often equated to H . As a further development to Heim’s Ratio, Parez & Aharonov (2015) then presented a functional model in which the contribution of spreading of the material is related to channel geometry as well as the surface angle of the final deposit.

The travel angle α_g is defined as the angle of declination between the centre of mass of the source volume and the centre of mass of the runout deposit (H_{COM}/L_{COM}) and has

Figure 1. Schematic illustration of flows in a simple planar flume, showing (a) definition of geometry statistics, (b) the case where the travel angle α_g is invariant with source volume, and (c) potential variation of α_g with changing source volume indicating a variation within the rheology.

78 been associated with an apparent friction coefficient (e.g. [Parez & Aharonov, 2015](#)). Con-
 79 ceptually, the travel angle may be invariant with source volume (Figure 1b), or it may
 80 vary with the source volume (Figure 1c) where scale effects are significant. Aggregated
 81 observations of historical debris flows, compiled by [Corominas \(1996\)](#) and [Rickenmann](#)
 82 [\(2011\)](#), illustrate the general trend of decreasing travel angle (signifying increased mo-
 83 bility and a decrease in effective flow resistance) as source volume increases. While there
 84 is a lack of consensus in the literature, collisionality (e.g. [Armanini 2013](#)), fragmenta-
 85 tion (e.g. [Bowman et al. 2012](#); [Caballero et al. 2014](#)), pore pressure diffusion length-scales
 86 (e.g. [Iverson 2015](#); [Kaitna et al. 2016](#)), and thermal effects (e.g. [Voight & Faust 1982](#);
 87 [Goren & Aharonov 2007](#); [Alonso et al. 2016](#); [Fischer et al. 2018](#)) amongst other hypothe-
 88 ses (e.g. effects at the laboratory scale such as side wall effects and air drag; [Bryant et](#)
 89 [al. 2015](#); [Kessler et al. 2020](#)) have been investigated as potential mechanisms through
 90 which larger volume landslides achieve higher mobility.

91 Experimental flume flows using dry granular material have shown that when the rheol-
 92 ogy of the flow is very simple, the runout behavior can be straightforwardly related to
 93 general physical parameters like slope angle, basal friction and grain size (e.g. [Mangeney](#)
 94 [et al. 2010](#)) or predicted (e.g. [Bryant et al. 2015](#)). Flows on fully saturated or initially
 95 saturated materials have shown rheological changes with source volume (e.g. [de Haas](#)
 96 [et al. 2015](#)), fines content or moisture content (e.g. [Kaitna et al. 2014](#); [Hürlimann et al.](#)
 97 [2015](#); [Zhou et al. 2018](#)).

98 Numerical simulations of landslide runout offer the ability to release a source volume,
 99 propagate its flow over a 2D or 3D geometrical representation of the terrain, and pro-
 100 vide estimates of inundation depth, velocity, and definition of the maximum distal reach
 101 of the debris for a given pairing of rheology and rheological parameters. Rheological mod-
 102 els are chosen based on the nature of the flow; in particular, to account for the effect of
 103 pore fluid. With the addition of an interstitial fluid to a granular flow, particles are sub-
 104 ject to both buoyancy and drag forces ([Armanini, 2013](#); [Iverson, 1997](#)). For a frictional
 105 continuum material, particle buoyancy serves to reduce the effective weight of the par-
 106 ticles, leading to reduced effective stress, and shear resistance, and hence, heightened mo-
 107 bility of the debris. In frequently used flow resistance models (e.g. simple friction or Voellmy
 108 model, in which a turbulence term is added to the frictional model to tune flow veloc-
 109 ity), pore pressure is considered implicitly. For a fully liquefied or low solids content flow,
 110 the effect of interstitial fluid may be more conveniently modelled as an equivalent fluid
 111 defined by a viscosity and yield strength (e.g. Bingham or Herschel-Bulkley rheology)
 112 for the duration of the flow. In both cases, pore pressure effects are typically considered
 113 to be constant during the duration of the flow. The validity of this assumption has been
 114 explored in [Tayyebi et al. \(2021\)](#), who suggest model choice should be guided through
 115 a consideration of two competing characteristic times: i) consolidation time and ii) prop-
 116 agation time. For scenarios in which the time of pore pressure dissipation is rapid in com-
 117 parison to the travel time, the high permeability debris is unlikely to retain excess pos-
 118 itive pore pressure, permitting simpler models of pore pressure effects to be used. On
 119 the other hand, it may be appropriate for fully undrained models to simulate lower per-
 120 meability flows, such as high water content slurries or liquefied debris. Debris flows with
 121 intermediate permeability between these two end members have the most computationally
 122 complex requirements for numerical simulation as the consolidation time and travel
 123 time can be of the same order.

124 The addition of an interstitial fluid is therefore recognized to have a dominant impact
 125 on the mobility of the flow. However, experimental studies in which both the bulk-scale
 126 (runout) and grain-scale behaviour of identical granular material in a dry and saturated
 127 initial state are directly compared are rare. If such a study were to be performed, it would
 128 provide a unique opportunity to test numerical simulation outcomes by first constrain-
 129 ing the frictional properties of the material (i.e. matching the runout behaviour of the
 130 dry experiments of different source volumes) before independently evaluating the imple-
 131 mentation of rheological models to account for buoyancy, fluid drag, and pore pressure

affecting the frictional material. The relative contributions of each mechanism may be revealed by matching the volume scaling effects.

In this manuscript we focus on the end member cases of high permeability debris which is initially dry or initially saturated with the objective of defining the influence of interstitial fluid and landslide volume on the runout distance and the relative contributions of translation and spreading in a material in which excess pore pressure is not expected to occur. A monodisperse material was used to ensure no segregation of particle size would take place during flow which could alter the rheologic behaviour, other than that caused by variation in solid and fluid concentration. Granular material was selected of a large enough grain size to isolate the effects of buoyancy and drag on the flows and allow for particle-level observation of contact behaviour and flow regimes. Dry flows of the identical source volumes were also tested as a direct point of reference for comparison.

In the remainder of the manuscript, we first describe the research flume, instrumentation, and high speed video analysis methods used for the experiments. The flow regimes of both dry and initially saturated 0.8 m^3 flows are then described and illustrated using representative frames and depth profiles. Next, velocity and volume fraction results are presented from the range of source volumes (0.2 to 1.0 m^3) to illustrate the variation in regimes. Finally, laser scanning results of the deposit morphology of each trial are used to explore the nature of the relationship between travel angle and source volume for both dry and wet flows.

2 Experimental Setup & Methodology

The experiments used a large indoor testing facility (Figure 2) and high speed imagery to investigate the mechanisms that lead to increased mobility when water is added to granular flows. The 2.09 m wide flume features a 8.23 m long section inclined 30° from horizontal and a 33 m long horizontal runout section. For the entirety of the inclined portion and for the first 3.68 m of the horizontal runout section, the base of the flume is constructed from bare aluminum and the side walls of the flume are glass to permit observation of the flows. Further down the flume, the base is constructed from smooth concrete. At the top, a release box with a hinged door can accommodate over 1.0 m^3 of saturated material. The door was rapidly opened using pneumatic cylinders to initiate the experiment, with the door moving clear of the material within 0.4 s . At the completion of the test, the final deposit shape was surveyed using a Faro Focus S 150 Light Detection and Ranging (LiDAR) scanner from two or more scanning positions.

2.1 Video Capture & Instrumentation

During the test, a Phantom v2512 high-speed camera was located near the end of the inclined portion of the flume (indicated as ‘CAM1’ on Figure 2) to capture mature flow behaviour in the travel stage. The camera was oriented in a side-on configuration to observe through the transparent glass side walls, rotated such that the width of the image was parallel to the base of the flume. The high-speed camera was set to capture a 1280×800 pixel greyscale image at a frame rate of $7,500 - 10,000 \text{ fps}$ (frames per second). A Tokina $100 \text{ mm f}/2.8$ Macro lens was used at its widest aperture to limit the depth of field and distinguish only the particles next to the glass side walls. The field of view was approximately 220 mm by 136 mm . A typical particle of 3.85 mm diameter was represented by a 23 pixel width in the resulting image.

Two initially saturated flows (0.4 and 0.8 m^3 source volumes) were repeated with the same high-speed camera and lens situated within the horizontal portion of the flume (‘CAM2’ on Figure 2). At this location, the camera was situated further back from the sidewall. The field of view was approximately 285 by 178 mm , with a typical particle represented by 17 pixels.

Nine fluid pressure transducer sensors were installed into the base of the flume to quantify the basal fluid pressure (Figure 2). The sensors (TE Connectivity model U5244-000002-

Figure 2. Diagram of (a) side profile, (b) oblique view, (c) top view of the experimental flume, illustrating the locations of high-speed camera fields of view, basal fluid pressure transducers, and ultrasonic height sensors.

14BG, 0 to 140 mbar range, manufacturer’s stated accuracy 7 mm, total error band 18 mm) were threaded directly into the flume. The fluid could enter each sensor through seven holes of 2 mm diameter.

Two ultrasonic distance sensors (model S18UUAQ, Banner Engineering Corp., 2.5 ms response time) were mounted above the inclined section of the flume, along the flume centreline (Figure 2). These sensors recorded the flow height away from the influence of the glass sidewalls by measuring the distance between the sensor and the top of the flow, normal to the flume base.

The sensor signals were sampled and recorded at 2000 Hz. During the experiments, the pressure sensors were subject to noise considered to be resonance of the flume. The natural frequency of the flume structure was measured at approximately 140 Hz. To counteract this noise, the pressure sensor output signals were filtered using a 80 Hz low-pass Butterworth filter.

2.2 Materials and Preparation

Pseudo-spherical ceramic beads, manufactured by Saint-Gobain Norpro and marketed as Denstone 2000 Support Media, were used as the granular material for the experiments. These beads were chosen for their pseudospherical shape, relatively uniform diameter, and ability to be reused for multiple trials with minimal breakdown. The physical properties of a representative sample of 30 beads were measured and tabulated by Coombs et al. (2019). The beads were found to have an average diameter of 3.85 mm, grain sphericity of approximately 95%, and grain density of 2241 kg m⁻³. According to the manufacturer, the hardness of the beads exceeds 6.5 on the Mohs scale. Triaxial tests conducted by Raymond (2002) gave effective friction angles of 33.7° at 20 kPa confining pressure.

The source volumes tested were comprised of 0.2, 0.4, 0.6, 0.8, and 1.0 m³. In each of the dry and initially saturated states, the material was made level in the release box using a rake. In the initially saturated state, the pore spaces were inundated with water but ponding water on top of the beads was minimized.

3 High-speed video analysis and calculated quantities

High-speed video was used to observe the flow structure and to provide images for further analysis. In this section, we discuss the image analysis methods used to identify the velocity and volume fraction for each test.

3.1 Particle displacement and velocity

The Particle Tracking Velocimetry (PTV) method involves first identifying the particle locations in selected frames and then using a PTV algorithm to link individual particles in successive frames (Brevis et al., 2010; Gollin et al., 2017; Taylor-Noonan et al., 2021). In our experiments, the camera is oriented to match the inclination of the flume base to optimise the field of view, e.g. so the particle movement vectors (Figure 3a) are generally horizontal in the illustrations. Thus, the direction of gravity is noted.

The images were analyzed in sets of fifty (50) images. Each set was initiated at an interval of $t = 0.05$ s during the passage of the flow. Within each set, the frames were selected from the video such that the frames were $\Delta t = .0004$ s apart (equivalent to 2,500 fps). For a particle moving at 5 metres per second, the movement was 11.5 pixels and the resulting ratio of particle movement per frame to particle diameter was 0.52. For a particle moving at 1 metre per second, the corresponding movement was 2.3 pixels. The results were grouped into bins to prepare depth profiles of the quantities, each drawn parallel to the flume base with height equal to one average particle diameter. Each vector was decomposed into components parallel and perpendicular to the flume base. Velocity profiles (Figure 3b) were calculated by averaging the components of each vector located within the bin, for all pairs of frames that comprise the set. The velocity of the lowest bin, adjacent to the flume base, was considered to be the basal slip velocity.

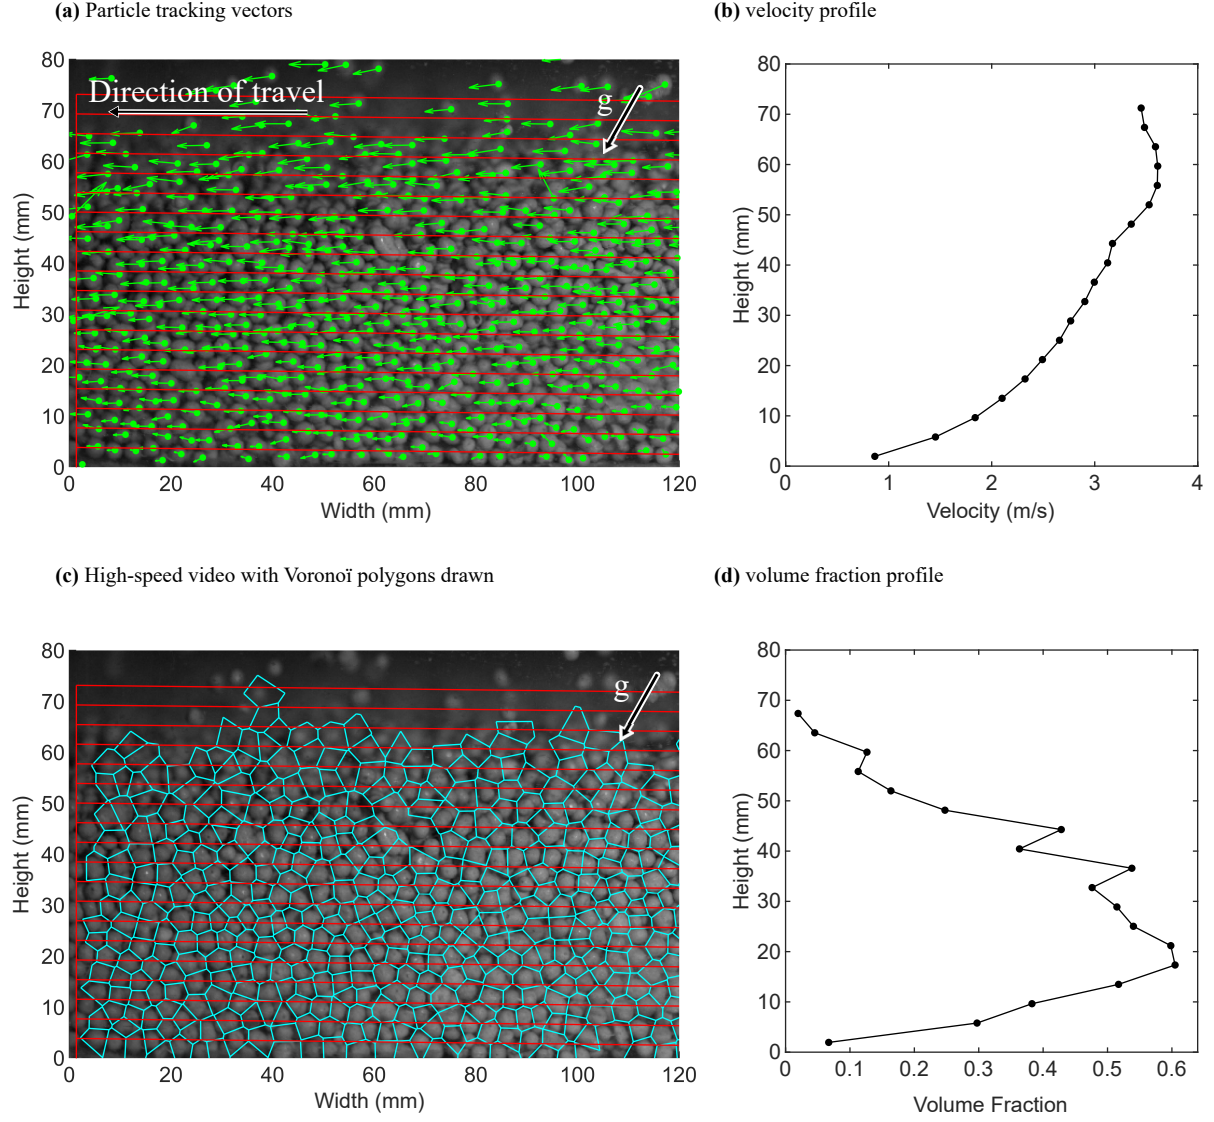

Figure 3. Representative video analysis and calculated profiles using PTV for 0.8 m^3 dry flow at peak flow height, illustrating (a) displacement vectors identified by PTV within bins drawn parallel to flume base (in red), (b) velocity profile calculated from displacement vectors within each bin, (c) Voronoï polygons drawn around particle locations for use in volume fraction estimation method, and (d) estimated volume fraction profile.

3.2 Volume Fraction

The volume fraction ν was estimated using the method proposed by Capart et al. (2002), which considers the size and shape of Voronoï polygons drawn around the identified particle locations as the basis of estimation. The image plane is divided into regions, each containing one identified particle centroid location (Figure 3c). The regions are drawn such that all points in the region are closer to that identified particle than any other.

This method uses a roundness parameter $\xi = 4\pi A/P^2$ where A and P are the area and perimeter of the Voronoï polygon around the particle, respectively. The roundness parameter ξ is calculated for all the particles in a bin over all the frames in each set. Voronoï polygons which share an edge with the analysis area of interest were disregarded, as the shape of these polygons may have been ‘clipped’ by the analysis area of interest. Before inclusion into the average, each Voronoï polygon was assessed for size and shape; Voronoï polygons with areas exceeding 2.5 times the area of an average particle or with a roundness parameter ξ below 0.70 were then discarded. Any polygon bordering a polygon which was discarded due to size or shape was not included in the average.

The volume fraction profile (Figure 3d) is estimated by:

$$\nu = \frac{\nu_{rcp} - \xi_0}{\xi_{rcp} - \xi_0} (1)$$

where indices “rcp” and “0” designate the state of random close packing and the dilute state, respectively. For random close packing of spheres, $\nu_{rcp} \approx 0.64$ (Allen & Thomas, 1999). Capart et al. (2002) performed a calibration study for volume fractions in the range $0.20 \leq \nu \leq 0.55$ and found calibration constants $\xi_{rcp} = 0.84$, $\xi_0 = 0.72$, and $\beta = 3.5$. This method was developed for the case where particles are observed against a rigid transparent wall, but calibrated with the average volume fraction in the cell. Thus, the method is expected to estimate the volume fraction away from the influence of the rigid wall.

For the purposes of further analysis and discussion in this paper, the flow height of the trials was set by the threshold, $\nu = 0.20$, over height and time (Figure 4). Some manual adjustments were made to exclude particles which were not immediately beside the sidewall glass. The top of fluid was manually marked on images at 0.05 second intervals for the wet flows.

4 Flow characteristics

We begin the comparison of dry and saturated flows through visual observations of flow structure, velocity, volume fraction, and pore pressure measured at the observation point near the end of the inclined section of the flume (the ‘CAM1’ location). The 0.8 m³ volume is chosen for this comparison of typical anatomy of the flows, with the variability observed in larger and smaller volumes and full analysis of the resulting deposit morphology explored in future sections of the manuscript.

4.1 Dry flow

The flow regimes within a 0.8 m³ dry flow are revealed by the velocity and volume fraction profiles as it passes the ‘CAM1’ location (Figure 5) at selected times t since door opening. The initial front of the debris flow is heralded by dilute, saltating particles (Figure 5a) with a (basal) slip velocity in excess of 2.5 ms⁻¹. A high level of collisional activity is seen when reviewing the video. The transition from collisional regime to frictional regime begins with a global reduction in speed. As the core approaches (Figure 5b), the volume fraction increases to approximately 0.32. The bottom of the flow slows due to friction with the base and the shear rate $\dot{\gamma}$ quickly increases. The slip velocity at $t = 1.74$ s is 1.8 ms⁻¹, while the surface velocity is 4.0 ms⁻¹ with a flow height of 36 mm.

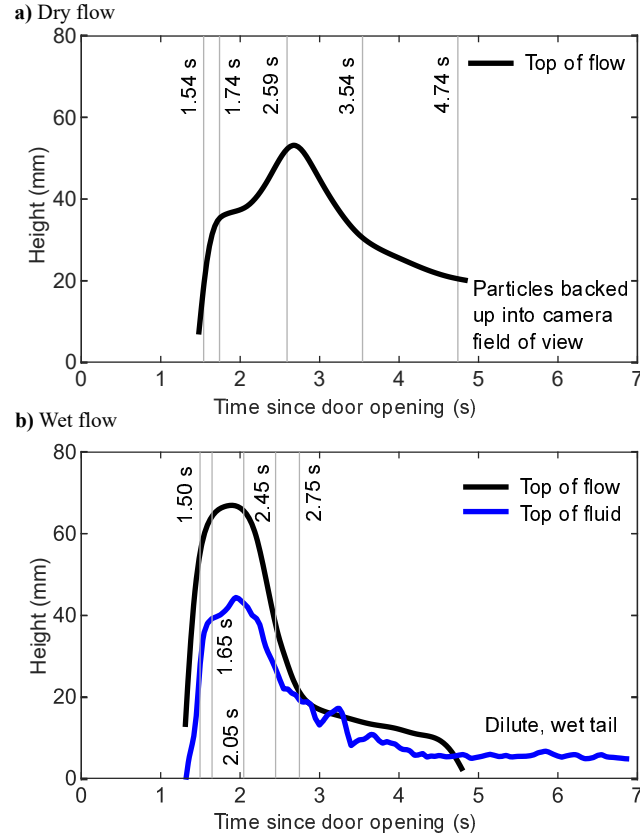

Figure 4. Flow heights vs time, at ‘CAM1’ location near the end of the inclined section of flume, for representative 0.8 m^3 (a) dry and (b) wet flows. The initially saturated flow is taller, has the majority of the mass biased towards the front of the flow, and has a long thin tail portion. The top of fluid is below the top of flow at the time of peak flow height.

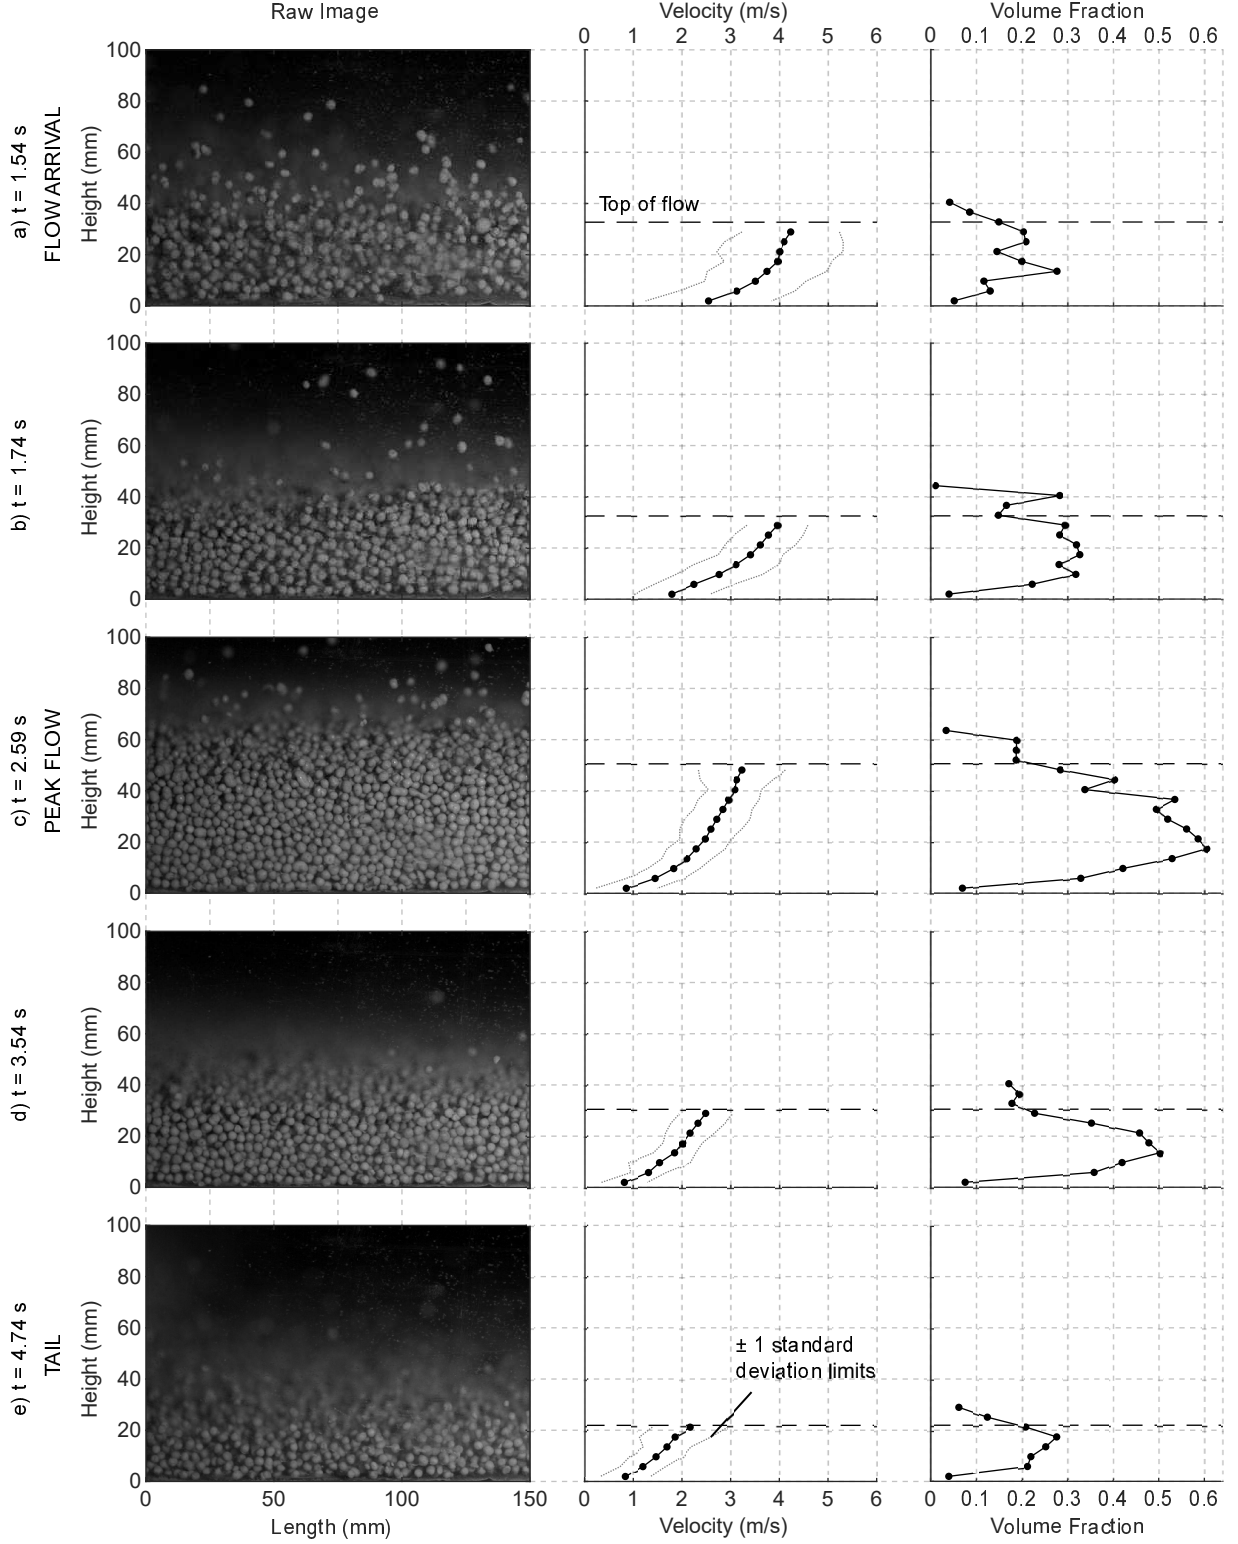

Figure 5. Anatomy of 0.8 m³ dry flow at end of inclined section of flume (‘CAM1’), showing a frame of video, the velocity profile with ± 1 standard deviation limits (in the 0.02 s observation time window), and the volume fraction ν at times (a) $t = 1.54$ s, (b) $t = 1.74$ s, (c) $t = 2.59$ s, (d) $t = 3.54$ s, (e) $t = 4.74$ s since door opening.

The peak flow height comprises a dense frictional core above a collisional base with a higher shear rate. The peak flow height of approximately 52 mm is visible at $t = 2.59$ s (Figure 5c). The volume fraction ν exceeds the ‘dense’ threshold of 0.49 (Jenkins, 2007) for the height interval between 16 and 39 mm in the core of the flow. The surface velocity is approximately 3.4 ms^{-1} , slower than at $t = 1.74$ s even though the flow height is higher. The slip velocity has reduced further to approximately 0.9 ms^{-1} .

The volume fraction reduces gradually and the pressure at the base reduces after the body of the flow passes (Figure 5d). At $t = 3.54$ s, ν ranges up to a maximum of 0.51. At $t = 4.74$ s (Figure 5e), the flow height has reduced to approximately 21 mm and ν has reduced to approximately 0.28. The slip velocity remains at 0.8 ms^{-1} and the surface velocity has reduced to 2.2 ms^{-1} . At $t = 4.85$ s, the determination of the velocity for the 0.8 m^3 flow is not possible as particles at rest begin to back up into the camera’s field of view. The runout morphology for this experiment is discussed in Section 6.

4.2 Saturated source volume

The typical behaviour of a fluid saturated flow is presented in Figure 6 for the 0.8 m^3 volume. The partitioning into a head section, frictional core, collisional base, and tail section is more pronounced for a wet flow than dry flow of the same volume. The front of the flow arrives before the fluid, similar to the unsaturated granular front observed in laboratory experiments by Leonardi et al. (2015) and Turnbull et al. (2015). In the early arrival stages of the core of the flow (Figure 6a), the top of fluid is seen at an approximate height of 30 mm while the flow height is approximately 43 mm. The free surface velocity exceeds 4.8 ms^{-1} , faster than the dry flow. The velocity profile shows a very high shear rate of approximately 200 s^{-1} near the flume base and minimal shear rate above the top of fluid. The flow is dilute, with identified volume fractions typically ranging between 0.3 and 0.4.

By $t = 2.05$ s, the flow height and the top of fluid are at their peak (Figure 6c), while the surface velocity has decreased to 4.5 ms^{-1} . The concentration of shear near the base of the flow continues. The density is less than the dry flow and is further reduced near the top of flow. Below the top of fluid, the maximum volume fraction, $\nu = 0.52$. In the portion of the flow above this, $\nu = 0.21$.

The top of fluid is coincident with the surface at $t = 2.75$ s (Figure 6e) and the tail of the flow is in view. The flow is dilute with $\nu = 0.32$. The slip velocity reduces from 1.6 ms^{-1} at $t = 2.75$ s to 0.4 ms^{-1} at $t = 4.00$ s, at which time the flow is only two particles high. This is in stark contrast to the tail end of the dry flows, where the slip velocity is seen to increase.

A similar, repeat, test was carried out for the 0.8 m^3 initially saturated flow, with the high speed camera set at the ‘CAM2’ location (Figure 2) on the horizontal runout portion of the flume. The results show that the flow arrives in a dense state at the residual water content with a free surface speed of approximately 2.6 ms^{-1} (Figure 7a), which is approximately half that at the time of peak flow at the upstream ‘CAM1’ position. The peak flow height is over 100 mm, approximately two-thirds greater than at ‘CAM1’. This shows that the material has laterally compressed following the change in slope. Shearing is concentrated near the base. The volume fraction generally exceeds $\nu = 0.5$ throughout the flow.

The top of fluid rises quickly to 102 mm above the flume base at $t = 2.40$ s (Figure 7b). A reduction in the volume fraction occurs simultaneously, especially near the top of the flow. As the core passes and the tail comes into view at $t = 3.00$ s (Figure 7c), the velocity decreases throughout the depth profile. The density increases in the lower portion of the flow. Later, the flow arrests completely while the tail is in the view of the camera.

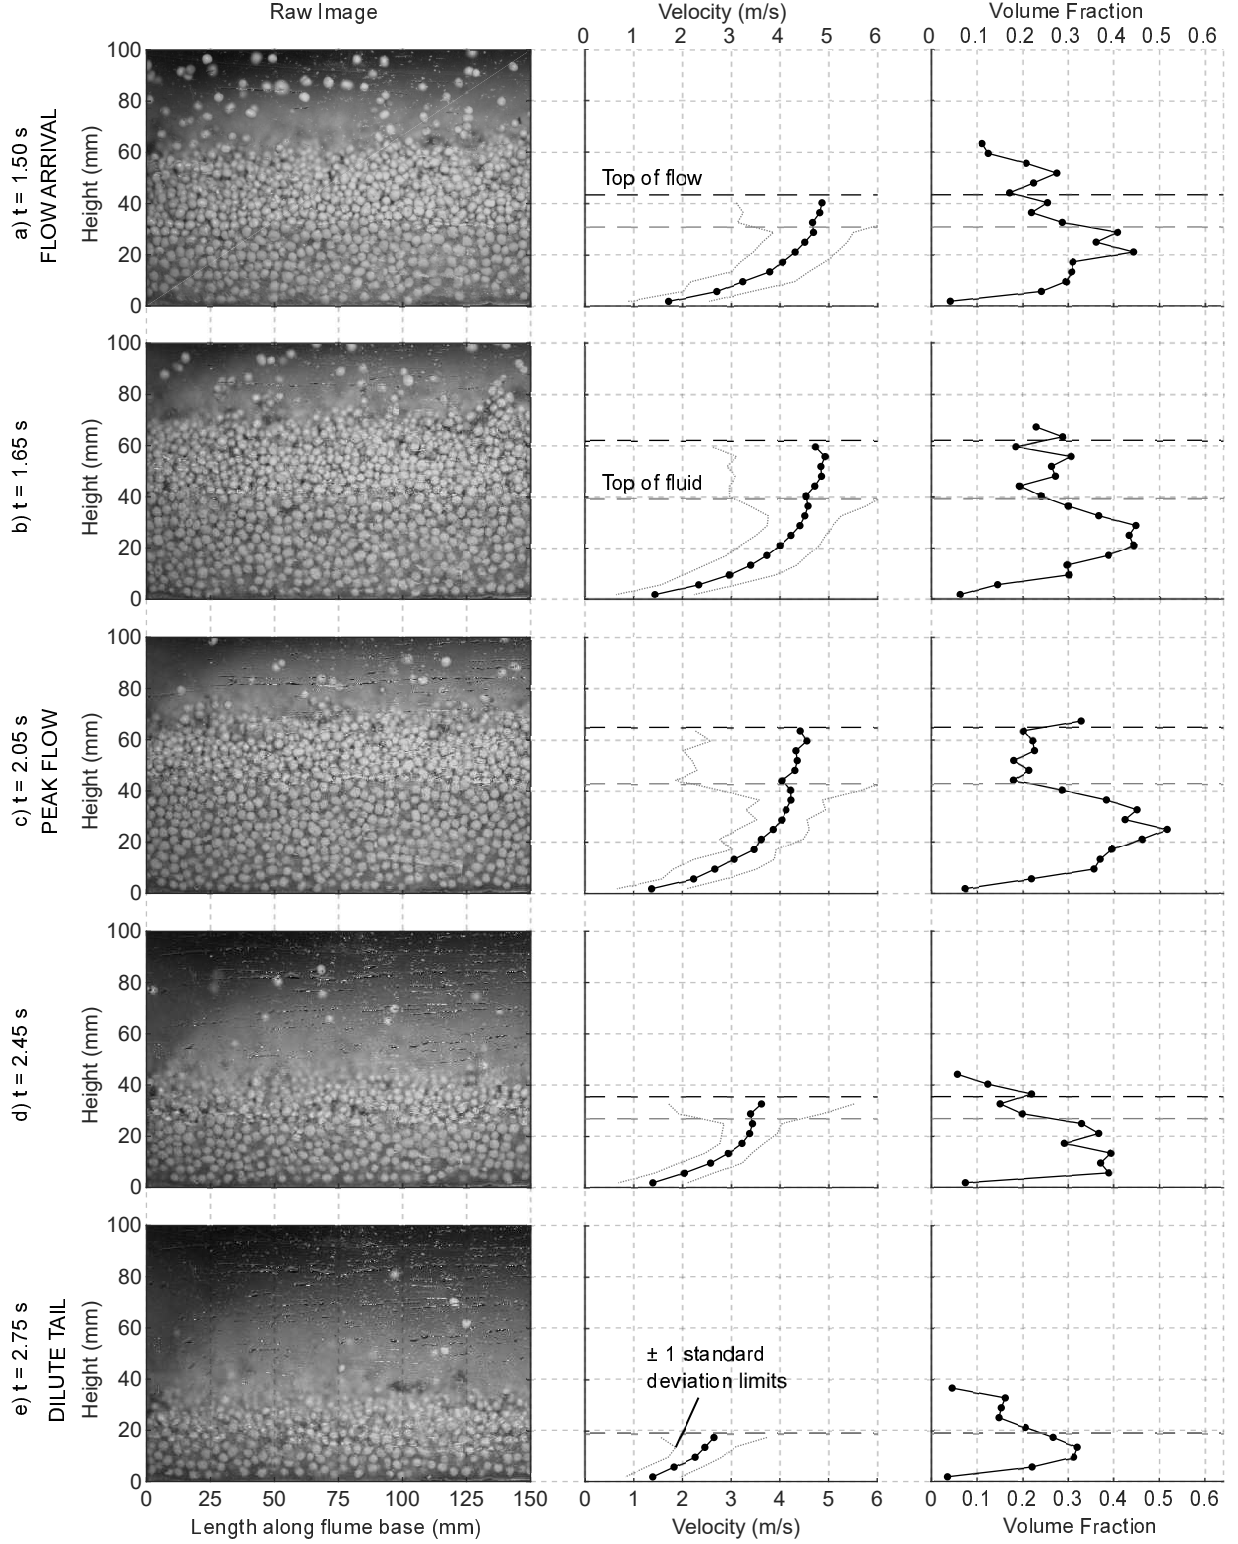

Figure 6. Anatomy of 0.8 m^3 initially saturated flow at end of inclined section of flume ('CAM1') showing a frame of video, the velocity profile with ± 1 standard deviation limits (in the 0.02 s observation time window), and the volume fraction ν at times (a) $t = 1.50 \text{ s}$, (b) $t = 1.65 \text{ s}$, (c) $t = 2.05 \text{ s}$, (d) $t = 2.45 \text{ s}$, (e) $t = 2.75 \text{ s}$ since door opening.

Figure 7. Anatomy of 0.8 m³ wet flow in horizontal runout section of flume ('CAM2') showing a frame of video, the velocity profile with ± 1 standard deviation limits (in the 0.02 s observation time window), and the volume fraction ν at times (a) $t = 2.15$ s, (b) $t = 2.40$ s, (c) $t = 3.00$ s, (d) $t = 3.50$ s since door opening.

4.3 Basal fluid pressures

During the initially saturated 0.8 m³ flow, the two laterally separated basal fluid pressure sensors on the inclined portion of the flume measure show similar peak pressure measurements. This leads to the conclusion that the flow is sufficiently mature at ‘CAM1’ to have recovered from the initial impulse of the granular collapse from the source box. The pressure traces from the centreline location to the side location at $x = +1.42$ m are also generally similar. When comparing the visually-identified flow height to the results of the ultrasonic flow height sensor, good agreement is seen between the centre and sides of the flow.

The visually-identified top of fluid at the side of the flow can be compared to the measured basal fluid pressure P at the centre of the flow, expressed as an equivalent bed-normal fluid height $H = P/\rho_w g \cos \theta$, where the density of water $\rho_w = 1000 \text{ kg} \cdot \text{m}^3$, the slope angle $\theta = 30^\circ$ and $g = 9.81 \text{ m} \cdot \text{s}^{-2}$. The equivalent height of the basal fluid pressure is equal to the the height of the fluid, indicating that the matrix fluid pressures did not exceed the equivalent hydrostatic regime.

The basal fluid pressures consistently increase across the four sensors situated on the horizontal runout portion. The highest pressures observed are at the furthest distance from the release box. This is attributed to the increasing flow height as the front of the flow slows and the rear of the flow cascades over. Good agreement is seen between the equivalent fluid height from the sensor at $x = +2.68$ m and the top of fluid. The wet flow is subject to contraction during the arrest phase but the basal fluid pressures do not increase above hydrostatic.

5 Effect of varying source volume

In this section, we expand on the comparison of dry and initially saturated flows using observations of flow thickness, velocity, volume fraction, and pore pressure measured at the observation point near the end of the inclined section of the flume (the ‘CAM1’ location) for source volumes ranging between 0.2 to 1.0 m³. This comparison is conducted to look at grain-scale mechanisms controlling the flow structure that may give rise to scale effects with flow volume.

5.1 Flow thicknesses and fluid pressures

As source volume increased through the tested range of 0.2 to 1.0 m³, the observed maximum flow thickness at $x = -0.50$ m (‘CAM1’) increased from 38 to 51 mm for the dry flows and from 30 to 79 mm for the initially saturated flows.

At shown in Figure 8 at $x = -0.50$ m, the maximum equivalent bed-normal fluid height (as calculated in Section 4.3) is equal to the peak flow height for the range of initially saturated source volumes tested. This suggests the matrix fluid pressures did not exceed the equivalent hydrostatic regime. The pore pressure ratio r_u , defined here as the ratio of fluid pressure to the total vertical pressure, ranges between [0.36 : 0.44].

5.2 Behaviour at peak flow height

In Figure 9, the time of peak flow height passing ‘CAM1’ is selected as a basis for comparison between the flows. This is the time when the flow is at its thickest and most dense state, and therefore the transport rate of mass is highest. A review of the profiles, discussed in detail below, provides information on the state of flow at the end of the incline as well as the partitioning of particles between highly shearing, lightly shearing, and collisional regimes.

At the time of peak flow height passing ‘CAM1’, the velocity profile of each of the initially saturated flows (“wet”) is faster than that of the dry flows. The overall velocity of the wet flows increases as source volume increases, with the top of the core of the 1.0 m³

Figure 8. Maximum flow thicknesses and fluid pressures observed at $x = -0.50$ m along centreline for initially saturated trials, with equivalent fluid height remaining below flow height over range of source volumes tested. The pore pressure ratio r_u is defined here as the ratio of fluid pressure to the total vertical pressure.

flow attaining a speed exceeding 5.0 ms^{-1} . Wet flows of all volumes are each seen to have a very high shear rate near the base of the flow. The opposite is noted for the dry flows, which are seen to be slower for each height in the flow as source volume increases.

At ‘CAM2’ after the change in slope, the 0.8 m^3 wet flow maintains this highly shearing flow which transports material (at residual water content) to the front of the flow. By comparison, the 0.4 m^3 wet flow displays minimal shearing at the same location.

Across the range of source volumes, the volume fraction profiles at the time of peak height passing ‘CAM1’ (Figure 9) for the dry flows display a similar shape as the 0.8 m^3 flow discussed above. The maximum volume fraction of the core increases with source volume. Each volume of wet flows displays a similar shape as the 0.8 m^3 flow, with a reduction in volume fraction above the top of fluid. The 0.2 through 0.6 m^3 dry flows each are entirely in a collisional regime when assessed by volume fraction. The 0.8 and 1.0 m^3 dry flows each have portions exceeding $\nu = 0.583$, indicating a frictional regime. While the maximum volume fractions of the wet flows increase slightly with source volume, the wet flows each have a lower maximum volume fraction than the dry flows of the same source volume and all remain in a collisional regime. For the dry flows, the volume fraction near the base is relatively consistent over the range of 0.2 to 0.8 m^3 . For the 1.0 m^3 flow, the dense region is seen to extend down to near the flume base, suggesting that the increased confining pressure of the thicker frictional core has suppressed the collisional base. The wet flows displayed a reduction in volume fraction near the base over the range of source volumes, coincident with a high shear rate.

5.3 Longitudinal distribution of regimes

Following the finding that the core region of the initially saturated flows appears to enter an efficient mode of transport that increases in velocity with flow thickness, the size of this core region relative to the total flow size is examined here. The partitioning into regimes along the length of the flow from head to tail can be assessed through plots of the measured quantities for each analysis interval and depth bin. Figure 10 shows the volume fraction results and Figure 11 shows the velocity results in a contour plot for-

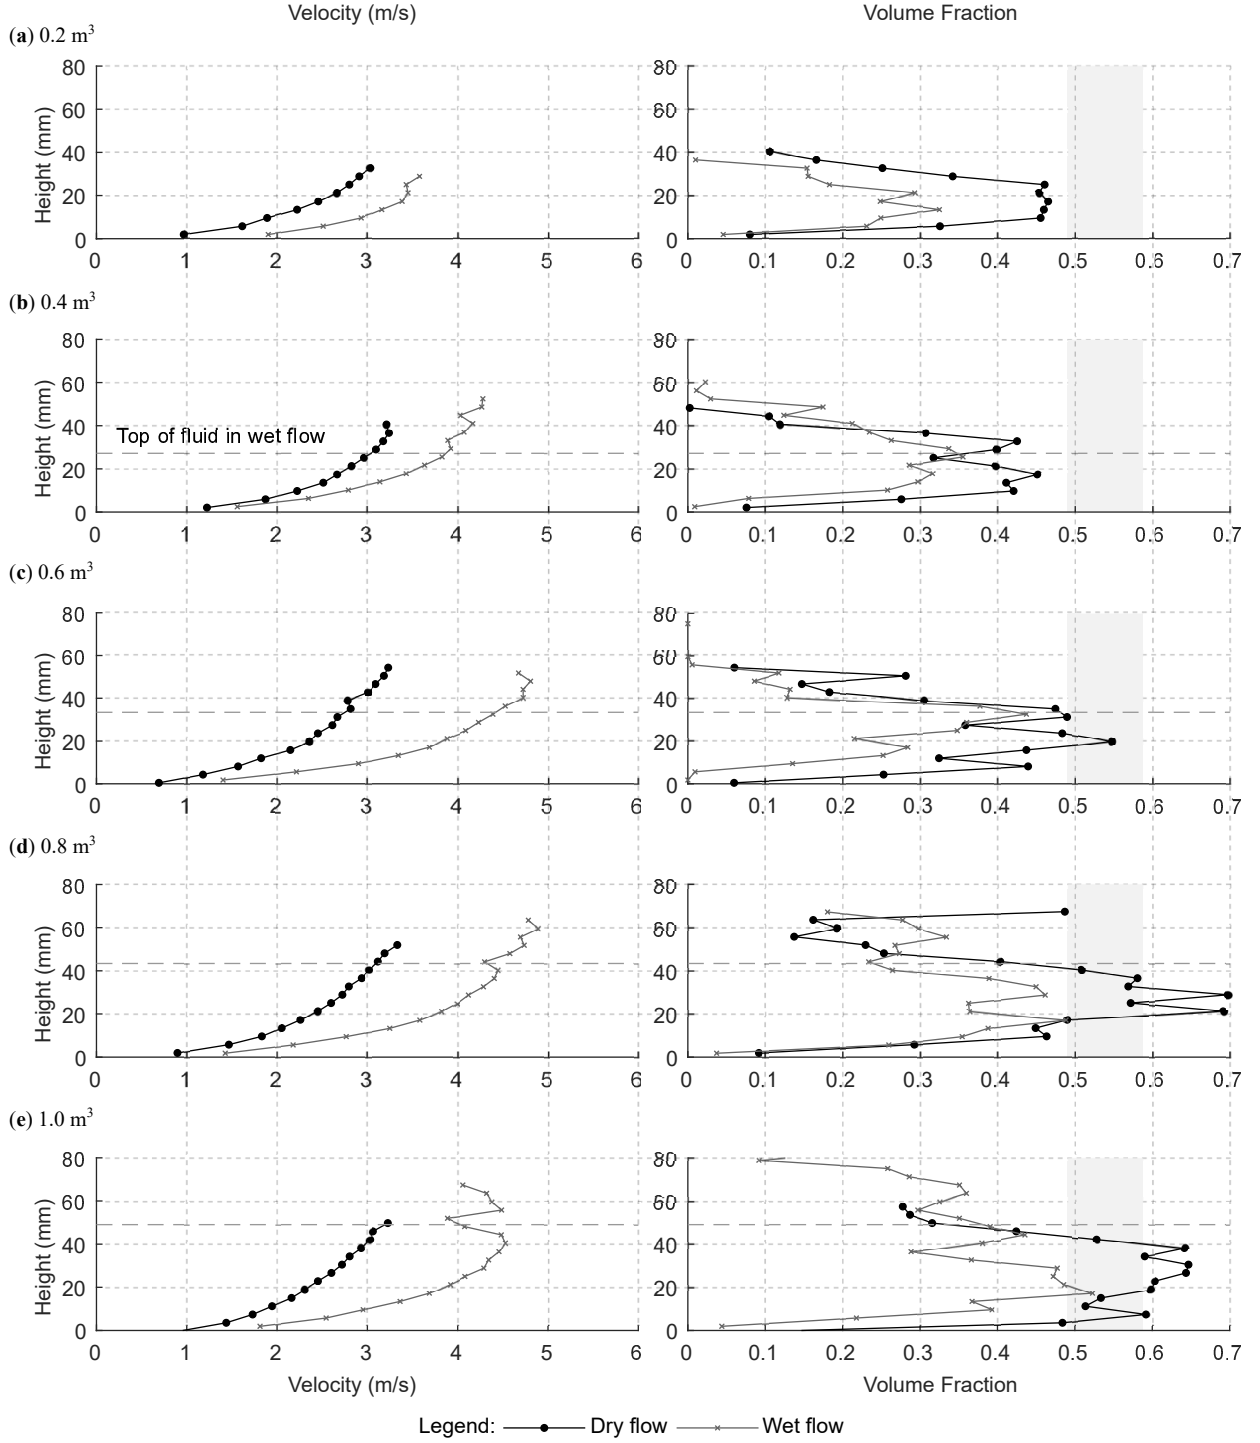

Figure 9. Comparison of depth profiles of streamwise velocity and volume fraction at the time of maximum flow height for (a) 0.2 m^3 to (e) 1.0 m^3 flows in 0.2 m^3 increments. The shading in the volume fraction plot represents the dense collisional regime ($0.49 \leq \nu \leq 0.583$).

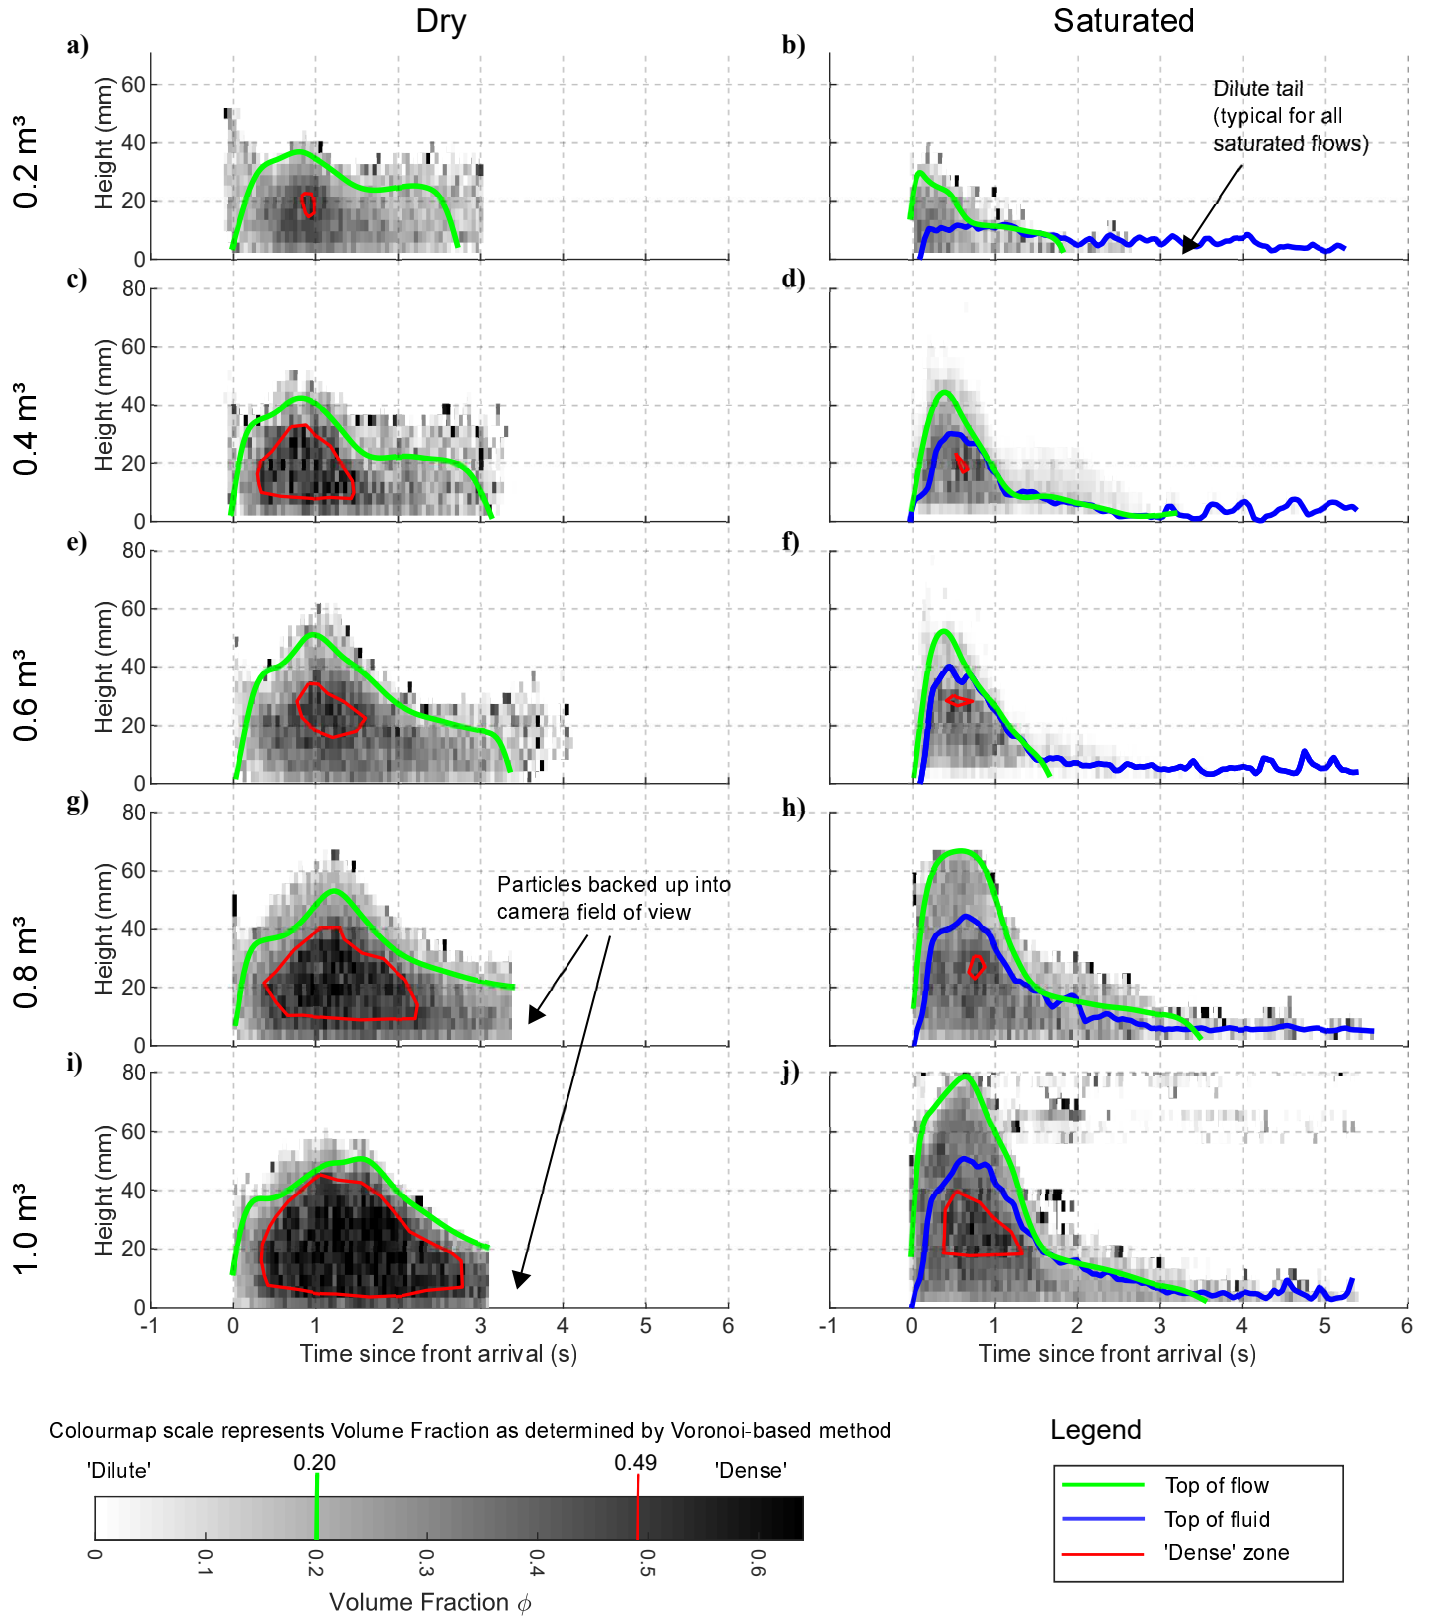

Figure 10. Height (y)-Time (x)-Volume Fraction (color scale) plots for for dry and saturated trials over the range of source volumes, illustrating the formation of a dense granular core for dry flows and a comparatively dilute core for wet flows. Both flows exhibit a reduction in volume fraction near the rigid flume base.

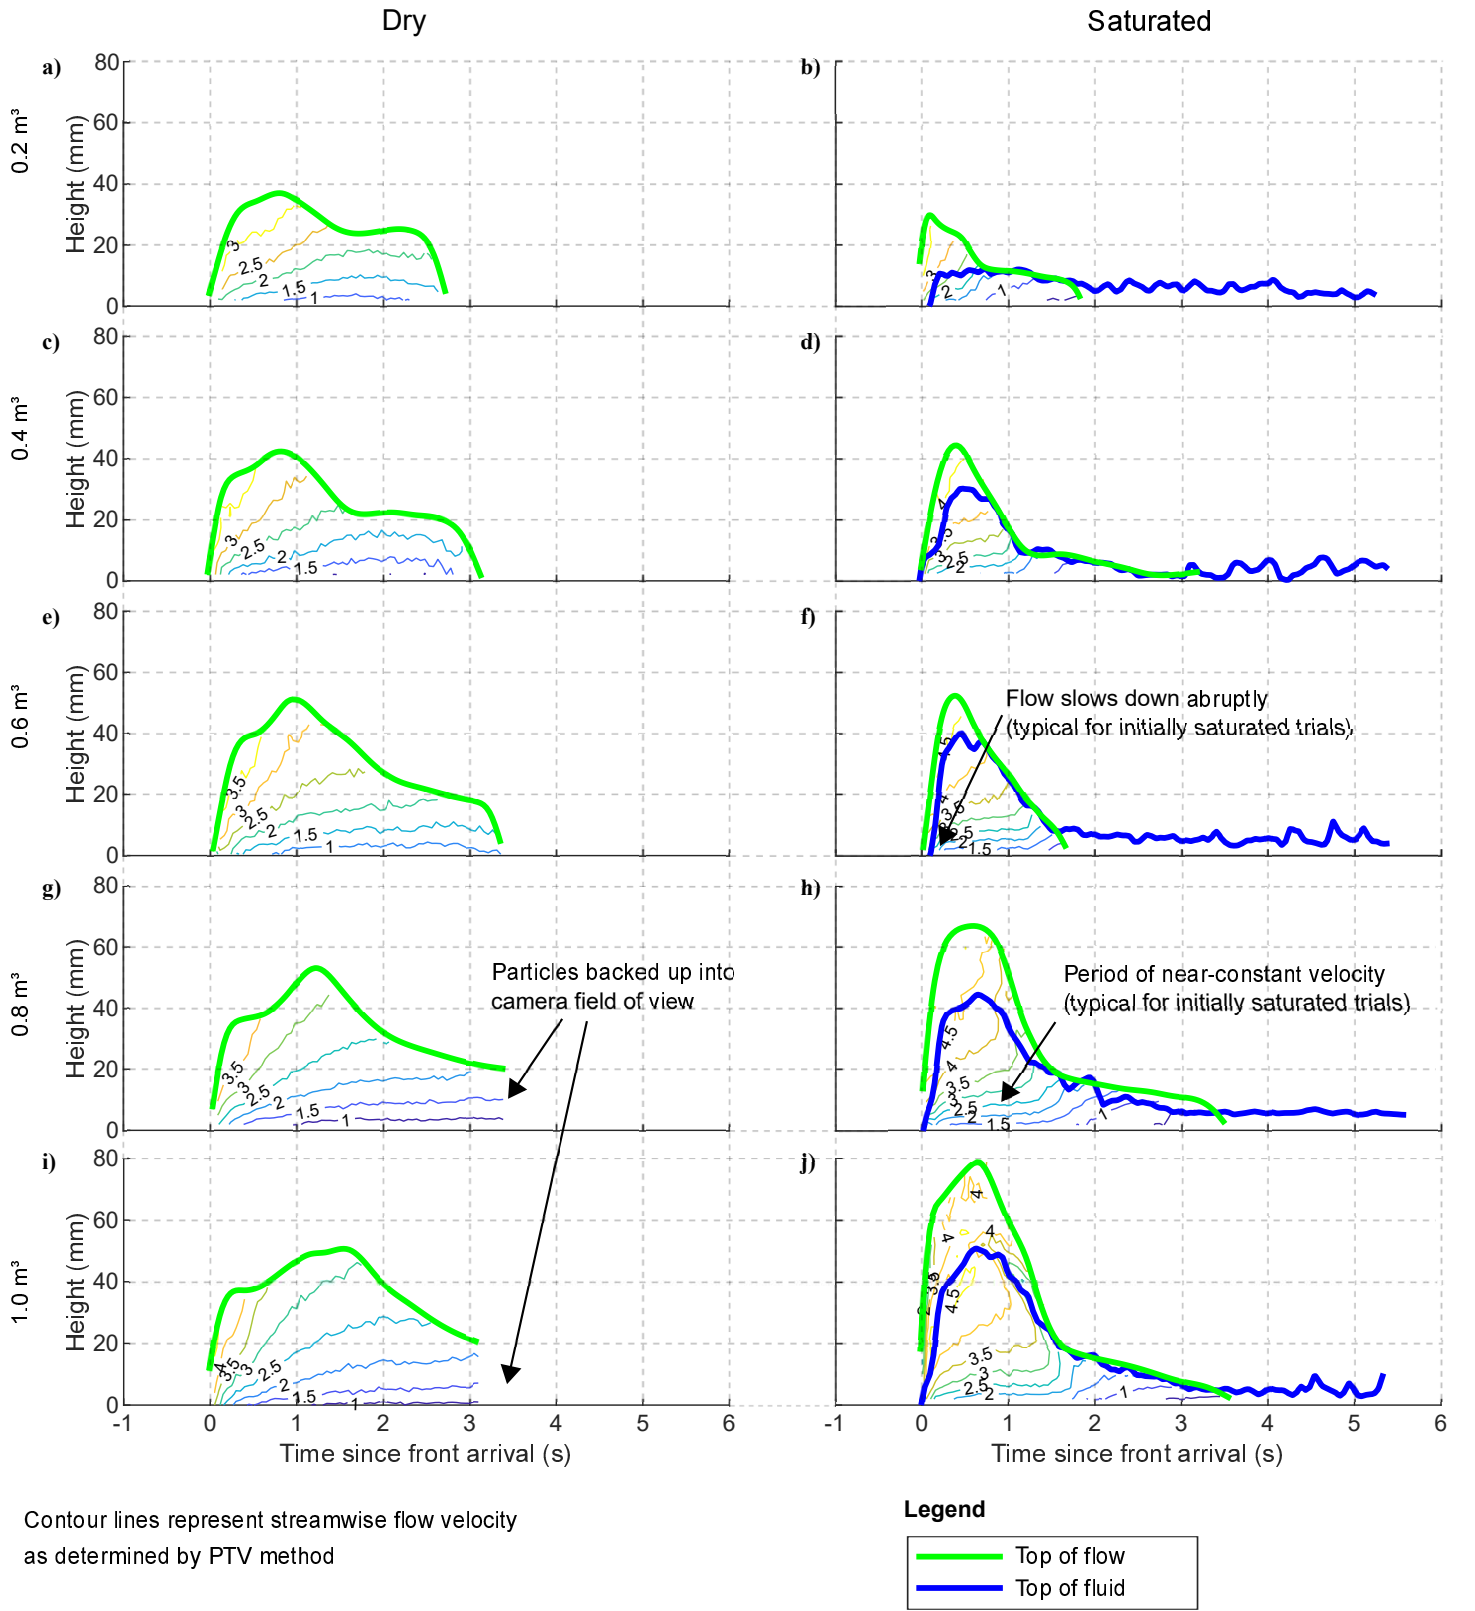

Figure 11. Height (y)-Time (x)-Velocity (color scale) plots for dry and initially saturated trials over the range of source volumes, illustrating the period of near-constant velocity near the base of the flume for the initially saturated state, suggesting that the flows find a ‘most efficient state’ for translation.

Figure 12. Comparison of basal slip velocities at end of incline for (a) dry trials illustrating the gradual decline in basal slip velocity and (b) initially saturated trials, illustrating a ‘step’ phenomenon where the velocity remains constant while the core passes, then quickly reduces to a slow speed ($<0.5 \text{ ms}^{-1}$) for the tail.

mat where the contour lines represent isovelocity lines. The shear rate can be inferred from the vertical distance between the isovelocity contour lines: isovelocity lines closer together represent a higher shear rate. Where the lines are parallel to the x-axis, that portion of the velocity profile is constant with time.

The volume fraction of the dry flows (Figure 10) shows partitioning of the flow into a dilute, saltating head preceding the front, a dense core where volume fraction increases with source volume, and a gradual reduction of volume fraction towards the tail. During this transition period, the velocity results show only gradual changes with time (Figure 11). Geometric similarity of the flow height over time is evident across the range of source volumes and the change in flow height between core and tail is gradual. In contrast, Figure 10 shows the saltating head is minimal to non-existent for the wet flows, while the regime of the tail is distinct from the core for both volume fraction and velocity (Figure 10 and Figure 11, respectively).

The initially saturated flows each display a period with near-constant velocity in the base of the flow (Figure 11), with the duration of this increasing with source volume. Only a short period of near-constant velocity in the base is observed within the 0.2 m^3 flow, increasing to 0.9 s for the 1.0 m^3 flow. The maximum shear rate near the base does not vary significantly with source volume, suggesting that the wet flows find and remain in a ‘most efficient’ state. This phenomenon is also visible on a plot of the slip velocity over time from the flow front (Figure 12) as a distinct plateau for the wet flows but not for the dry flows.

The wet flows slowed down significantly from core to tail in contrast with the dry flows, which slowed down less significantly. An effect for the deceleration of the wet flows is thought to be due to surface tension between the liquid phase with the flume base and sidewalls. At this stage, the tail portions of the initially saturated flows are slow moving and of low

(a) Dry trials

(b) Initially saturated trials

Figure 13. Comparison of resultant deposit morphology profiles for (a) dry and (b) initially saturated trials, with calculated centres of mass indicated.

volume fraction and minimal thickness. Some ceramic beads remained on the flume surface at the end of the experiments until the remnant water evaporated. The material partitioned to this slow-moving tail would reduce the volume available to be transported at high speed in the core section of the flow. This is in accordance with the description of ‘starving’ avalanches by Bartelt et al. (2007).

6 Variation of morphology of resultant deposit with source volume

The observations of grain-scale phenomena clearly illustrate that the granular flow structures evolve with volume, and more so for the wet than dry flows. In this section, we explore the consequences of these differences in grain scale behaviour, as seen in the deposit morphology.

The deposit morphology for each of the five dry and five saturated flow volumes, captured using LIDAR scanning, is presented in Figure 13. The profile of deposit morphol-

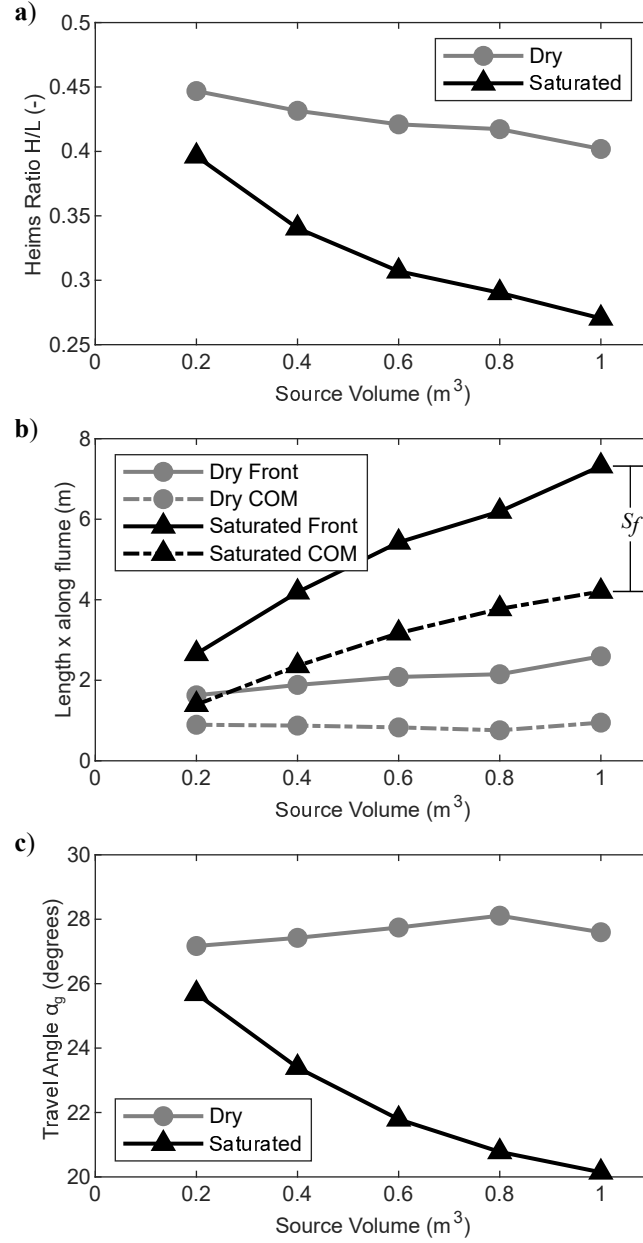

Figure 14. Comparison of summary statistics of mobility, showing (a) Heim's ratio from top of source volume to distal reach of deposit, (b) position of front extent of deposit and centre-of-mass of deposit, illustrating the relative contributions of each to total runout, and (c) travel angle between centres of mass.

ogy illustrates geometrical similarity over the range of source volumes for dry flows, in agreement with the model postulated by Perez & Aharonov (2015). In contrast, the initially saturated flows display markedly increased runout distances as source volume increases. Runout statistics, illustrated schematically in Figure 1a, can be used to summarize the resultant deposit morphologies (Figure 14). The frontal extents of the flow are considered in Heim's Ratio H/L (Figure 14a). Heim's Ratio remains relatively constant for dry flows but decreases significantly for initially saturated flows, indicating increased mobility with volume. The forward spread S_f of the deposit is the distance between the the centre-of-mass and front extent of the deposits (Figure 14b). A slight increase in the forward spreading distance is seen for dry flows, commensurate with geometric similitude. For the initially saturated flows, a much larger increase of the forward spreading distance with volume occurs, the majority of which is from translation of the centre-of-mass.

The travel angle statistics summarize the translation of the centre-of-mass (Figure 14c), with a lower travel angle indicating a general increase in mobility. For the dry tests, a relatively consistent travel angle of 27.1° to 28.1° was calculated over the range of source volumes tested. For the wet tests, the travel angle reduced significantly from 25.7° for a source volume of 0.2 m^3 to 20.1° for a source volume of 1.0 m^3 . This marked decrease indicates that one or more physical processes within the rheology of the wet flows are affected by experiment size.

7 Conclusions

A series of monodisperse granular flows was released within a large laboratory flume to define the effect of landslide volume on the runout distance and the relative contributions of translation and spreading in a material in which excess pore pressure is not expected to occur. Both dry and initially saturated states were tested and the source volume was systematically varied from 0.2 to 1.0 m^3 in 0.2 m^3 increments. The use of high permeability debris retained the possible influences of particle buoyancy and fluid drag but was confirmed to not result in basal fluid pressures that exceed hydrostatic conditions. The tests exhibited marked differences in runout distance and flow regimes as observed by high-speed video between dry and initially water saturated conditions.

The dry flows were heralded by a region of saltating particles, followed by a dense, frictional core, the density and extent of which increased with source volume. The velocity quickly slowed as the frictional core arrived. Through the range of source volumes, it was observed that the velocity at the time of peak flow height was highest for the smallest source volume and lowest for the largest source volume, throughout the flow depths. The particle velocity was then seen to increase after the passage of the core.

Distinct regimes were seen within the initially saturated flows, with differentiation not only from the head to tail of the flow but also with flow depth. The front of each of the initially saturated flows was comprised of particles at residual water content, which had broken free of the fluid matrix. At the time of peak flow height, the velocities of the initially saturated flows were each faster than that of the dry flows and were generally faster as source volume increased. The top of fluid was below the top of the flow at the time of peak flow height indicating that a significant mass of particles was transported at residual water content, at high speed. The density of the core of the initially saturated flows also increased with source volume, but was lower than the dry flows of the same source volume.

The initially saturated flows each demonstrated a period of near-constant velocity with high shear rates near the base of the flows. This is interpreted to be a 'most efficient' flow regime. The length of this period increased with source volume. After the core of the flows passed, the flow velocities rapidly decreased to rates lower than observed in the dry flows, presumably due to surface tension between water and the flume.

The consequences of these differences in grain-scale interaction can be quantified through an assessment of the resulting deposit morphology and the relative contributions of translation and spreading to the total runout length. For the dry flows, the travel angle increased very slightly from 27.1° to 28.1° (indicating slightly decreased mobility) for larger source volumes of dry material. This suggests that the effective friction at the base increased with the denser frictional cores due to increased confining pressure. For wet flows, the mobility increased significantly from 25.7° to 20.1° as source volume increased. This increase in total mobility was seen to come more from translation of the centre-of-mass than spreading at the front. This confirms that significant scaling effects are present within multiphase granular flows, even without the presence of ‘excess’ pore pressures. The experimental data suggests that this is, in part, due to the partitioning of the source volume into a highly shearing base and a slow tail section. The remainder of the source volume is transported very quickly above the base, and is the prime contributor to the long runout distances observed. The experiments demonstrate that even with a coarse granular material, the effects of the interstitial fluid and partitioning into flow regimes can lead to scaling effects as flow thickness varies. This data provides additional support to the conclusion that flume size matters, particularly for fluid saturated flows. The critical processes within multiphase granular flows are complex and localized, and physical experiments linking particulate behaviour to bulk response are required to fully validate and calibrate conceptual and numerical models.

This study begins to address the paucity of such experiments through the publication of a unique dataset that combines the detailed grain-scale visual observations of flow structure, velocity, and volume fraction, with the observed consequences in terms of effective friction and debris spreading. This unique dataset is publicly available on the Scholarportal Dataverse repository to serve as a well-defined test scenario to assess the role of interstitial fluid in numerical runout models of debris flows.

Open Research

The data used in this research are archived in the Queen’s University Dataverse (<https://dataverse.scholarportal.> A Dataverse entry will be created for the dry and saturated granular flows and made accessible at a DOI at manuscript acceptance.

Acknowledgments

This project is the result of a Leverhulme Trust International Network Grant (#IN-2016-041) “The Rosetta Stone Network: Physical testing towards a common understanding of debris flows”. Funding for the first author provided by a NSERC Discovery Grant to the last author.
