Key Points:

- A new method is applied to infer urban water storage capacity from evapotranspiration recession.
- Our observational analysis of evaporation over cities worldwide reveals strong water limitation.
- Water storage capacity in cities is an order of magnitude smaller than in natural systems.

Abstract

Water storage plays an important role in mitigating heat and flooding in urban areas. Assessment of the water storage capacity of cities remains challenging due to the inherent heterogeneity of the urban surface. Traditionally, effective storage has been estimated from runoff. Here, we present a novel approach to estimate effective water storage capacity from recession rates of observed evaporation during precipitation-free periods. We test this approach for cities at neighborhood scale with eddy-covariance based latent heat flux observations from fourteen contrasting sites with different local climate zones, vegetation cover and characteristics, and climates. Based on analysis of 583 drydowns, we find storage capacities to vary between 1.3–28.4 mm, corresponding to e-folding timescales of 1.8–20.1 days. This makes the storage capacity at least one order of magnitude smaller than the observed values for natural ecosystems, reflecting an evaporation regime characterised by extreme water limitation.

Plain Language Summary

Urban water storage plays an important role in mitigating urban flooding and affects urban heat via cooling through evapotranspiration. Determining the amount of water that can be stored in a city remains challenging due to the variability in urban landscapes. The methodology presented estimates this water storage based on how evapotranspiration declines over time during periods without precipitation. The estimated storage capacities amount to 1.3–28.4 mm, which is an order of magnitude smaller than in natural ecosystems.

1 Introduction

With a large and growing share of the world population living in cities (United Nations, 2018), the impact weather-related risks magnified by climate change, such as heatwaves and flooding (Wilby, 2007), also increases. In cities, air temperatures are typically higher than in the rural surroundings due to the Urban Heat Island effect (UHI) (Oke, 1982; Santamouris, 2014; Oke et al., 2017). The UHI originates from the difference between the rural and urban energy balances due to lower albedo, radiation trapping, less vegetation, higher heat storage capacity and anthropogenic heat release (Oke, 1982). Because of its positive effect on evaporative cooling that is complemented by shading, urban vegetation is often given a central role in attempts to improve thermal comfort (Ennos, 2010). Indeed, higher vegetation fractions are associated with lower urban air and canopy temperatures (e.g. Gallo et al., 1993; Weng et al., 2004; Theeuwes et al., 2017), although in specific situations vegetation can cause higher temperatures (Meili et al., 2021a). Wei and Shu (2020) showed that expanding the vegetation fraction as part of urban renewal can improve thermal comfort. However, vegetation-mediated cooling strongly depends on water availability for evapotranspiration (ET) (Avissar, 1992; Manoli et al., 2020).

The generally low ET over urban areas also reflects a different water balance that makes cities more prone to flooding. A high impervious surface fraction promotes storm water runoff, which can accumulate relatively fast (Arnold Jr & Gibbons, 1996; Fletcher et al., 2013). Consequently, high runoff ratios decreases water availability for ET, and thus indirectly contributes to the UHI (Taha, 1997; Zhao et al., 2014). Heavy rainfall in cities can lead to flood volumes that are 2–9 times higher than in rural areas (Paul & Meyer, 2001; Hamdi et al., 2011; Zhou et al., 2019), often causing considerable damage (Tingsanchali, 2012). Solutions to problems related to the urban water and energy balance have been proposed under various names such as Water Sensitive Urban Design (Wong, 2006), Low Impact Development (Qin et al., 2013), Sustainable Drainage Systems (Zhou, 2014), Sponge Cities (Gaines, 2016), and Nature Based Solutions (Somarakis et al., 2019). All these concepts promote increasing infiltration and effective storage capacity, of which the latter is crucial for their performance (Graham et al., 2004; Qin et al., 2013). Therefore, methods to assess effective storage in cities at urban landscape scale are needed.

Estimation of the urban water storage capacity is challenged by the heterogeneity of sources for ET (Sailor, 2011). Previous studies have mainly focused on ET from individual sources (e.g. Gash et al., 2008; Starke et al., 2010; Pataki et al., 2011; Ramamurthy & Bou-Zeid, 2014), as well as on their combined behaviour at street or neighborhood scale (e.g. Christen & Vogt, 2004; Jacobs et al., 2015; Meili et al., 2020, 2021b). In order to study the ET on a neighborhood scale (order of hundreds of meters to 1–2 kilometers), flux measurements of with their associated footprint through eddy covariance or scintillometry, are becoming increasingly popular. Due to relatively large footprints, urban EC measurements often reflect a myriad of sources including impervious surfaces, vegetation, open water and all other sources of ET. Hence, in this paper an urban surface is defined as the entire urban landscape found within the footprint, rather than impervious surface only. This is in line with many studies on urban ET from an EC perspective, since the ET sources cannot be separated (e.g. Coutts et al., 2007b; Vulova et al., 2021). In contrast, modelling-oriented studies are able to make this separation and thus often use urban and impervious interchangeably (e.g. Masson, 2000; Wouters et al., 2015). Examples of cities for which EC measurements have been studied are Arnhem (Jacobs et al., 2015), Basel (Christen & Vogt, 2004), Helsinki (Vesala et al., 2008), Melbourne (Coutts et al., 2007b), Seoul (Hong et al., 2019) and Singapore (Roth et al., 2017). Under water-limited conditions, ET observations contain information on storage (Teuling et al., 2006). In one of the few studies directly linking urban ET and storage, Wouters et al. (2015) applied this principle to validate a new parametrization for the impervious contribution to urban water storage in Toulouse. However, the link between ET and footprint-scale urban water storage remains largely unexplored.

Recession analysis can be used to link eddy-covariance flux observations and storage properties. From the 1970s, discharge recession analysis has been extensively used in groundwater and hillslope hydrology (e.g. Brutsaert & Nieber, 1977; Kirchner, 2009; Troch et al., 2013). Similarly, daily ET values can be linked to water storage during a drydown, a period without precipitation creating water-limited conditions. Assuming that the ET decay is exponential, the e-folding time, or the timescale over which ET declines by 63%, reflects the available storage and resilience to droughts (Wetzel & Chang, 1987; Salvucci, 2001; Saleem & Salvucci, 2002). Since the storage is inferred directly from ET observations, this water storage is defined as the dynamic water storage capacity available to the atmosphere for ET, which includes soil moisture, intercepted precipitation and open water varying from lakes to puddles. As a result of plant-physiological processes, this storage is not necessarily constant (Dardanelli et al., 2004). In studies using daily ET over natural ecosystems, Teuling et al. (2006) and Boese et al. (2019) found timescales ranging from 15 days for short vegetation to 35 days for forest ecosystems, and corresponding storage capacities of 30–200 mm, with most sites in the range of 50–100 mm. A global-scale analysis of surface soil moisture recession by McColl et al. (2017) found timescales ranging from 2 to 20 days. Although valuable insight can be obtained from a comparison of urban and rural ET dynamics, recession analysis has not yet been applied to urban ET.

In this study, we extend the methodology developed by Teuling et al. (2006) to estimate footprint-scale water storage capacity directly from EC observations of daily ET in cities without modeling ET itself. The methodology is applied to a new, unique collection of urban ET data containing cities in a range of climate conditions and with different urban land cover and structure. This allows for a first assessment of urban storage capacity across cities, an evaluation of how site characteristics (e.g. vegetation fraction) affect water storage, and a comparison of urban water storage to that of natural ecosystems.

2 Data and Methods

We analyze latent heat fluxes and auxiliary meteorological data from eddy covariance flux towers at fourteen sites in twelve different cities to estimate water storage. Table 1 lists a number of important characteristics of each site, including key references. In these references, all observation sites and measurement details are fully described. The sites were selected based on the length of the data record (minimum of a year), flux footprints representing typical urban neighborhoods without other land covers, and the availability of observed precipitation and latent heat fluxes. All sites are located in reasonably flat terrain. Most sites were located in mid-latitude climates, except Mexico City with a subtropical climate, Singapore with a tropical climate, and Helsinki, Łódź and Seoul with a continental climate. Vegetation fractions in the associated footprints vary between 6–56%.

Observations were reported in averaging periods of 10–30 min depending on the measurement protocol of each site. In this study, hourly averages were used to determine the timing of rainfall and 24-hour averages were used for the recession analysis. For all sites the quality control of the observed heat fluxes was performed by individual researchers responsible for their ET flux observation site. Although the exact methodology of the quality control differs per site, all fluxes have been properly tested in accordance with procedures published in literature (Aubinet et al., 2012).

During multi-day drydowns in urban areas without rainfall, runoff is typically minimal after a steep peak shortly after rainfall (Walsh et al., 2005; Fletcher et al., 2013). Therefore, the evolution in landscape-scale dynamic storage (S) over the whole drydown can be simplified as:

$$\frac{dS(t)}{dt} = -\mathrm{ET}(t) \tag{1}$$

Under water-limitation, daily ET becomes a function of storage. For impervious surfaces in cities, the storage dynamics have been described by a $\frac{2}{3}$-power function resulting in depletion within a few hours of daytime (Masson, 2000; Ramamurthy & Bou-Zeid, 2014). ET from other sources will likely show different behavior (Granger & Hedstrom, 2011; Nordbo et al., 2011), with ET from (urban) vegetation behaving more as a linear reservoir (Williams & Albertson, 2004; Dardanelli et al., 2004; Peters et al., 2011). Since impervious surfaces are typically quickly depleted, open water is constant and vegetation behaves more linear, we assume the flux footprint reflecting a mixture of different ET sources to effectively behave as a linear reservoir:

$$\mathrm{ET}(t) = f(S(t)) = cS(t) \tag{2}$$

in which $c = 1/\lambda$ is a proportionality constant. Combining Eq. 1 and Eq. 2 and solving the differential equation leads to an exponential response of ET:

$$\mathrm{ET}(t) = \mathrm{ET}_0 \exp\left(-\frac{t - t_0}{\lambda}\right) \tag{3}$$

where λ is the e-folding timescale, and ET_0 the initial ET. With these parameters the total dynamic storage volume S_0 in mm that would be depleted during a complete dry down ($t \to \infty$) is given by:

$$S_0 = \int_{t_0}^{\infty} \mathrm{ET}(t)\mathrm{d}t = \lambda \mathrm{ET}_0 \tag{4}$$

Table 1. Site characteristics and summary of regression analysis. The climate statistics are long-term means (1999–2019). so that S_0 can be estimated by fitting observed ET in time during a drydown, without modeling the flux. Because of this direct inference without an imposed model structure, the shape of the fit has minimal influence on the results. To further tailor this concept to urban environments, the anthropogenic moisture flux can be included. This flux can contribute substantially to ET, in particular during long, dry periods (Grimmond & Oke, 1986; Moriwaki et al., 2008; Miao & Chen, 2014), and includes processes like transport, heating, cooling (indoor), human metabolism and irrigation, which do not directly depend on rainfall. Variation in the daily averages of these processes, except for irrigation, can be expected to be negligible over the course of one drydown. Thus, to account for these processes we added a constant base term to Equation 3. Since this yields parameters in compliance with the requirements explained below for only one drydown, we conclude that including this part of the anthropogenic moisture flux does not improve the physical representation of the city. As mentioned earlier, irrigation cannot be expected to be constant, while in some cities (e.g. Vancouver (Grimmond & Oke, 1986; Järvi et al., 2011) and Melbourne (Barker et al., 2011)) its contribution to ET can be considerable during long dry periods. We adapt the methodology in two ways to prevent irrigation affecting the results. First the chance of irrigation decreases with a maximum duration of a drydown of 10 days. This also reduces the influence of the tail of the drydown on ET_0. Second we require an R^2¿0.3, which is not achieved if irrigation causes ET to suddenly rise.

To estimate the parameters λ and ET_0, we identified all periods without precipitation for at least three continuous days, the minimum requirement for an exponential fit (Figure 1). In order to preserve the information in ET during the first hours after rainfall (in case of low λ), we start the 24-hour averaging bins directly after the rainfall event, regardless of its magnitude. The bin-average is assigned to the middle of the day (e.g. the first bin is assigned to 0.5 day since rainfall). We exclude hours with an average shortwave incoming radiation below 10 $\mathrm{W\,m^{-2}}$ (i.e. nighttime), since during the night ET tends to be low. No gap-filling was applied, and only bins with at least 70% of data for daytime hours were analyzed. For the longest time series (Basel (KLIN)), requiring 70% instead of 100% increased the sample size by 48% respectively, while the median of the water storage capacities only changed by 25%. Further lowering the threshold did not increase data availability. Given the minimal effect on the results and potential to increase the sample size, 70% provides more information especially regarding cities with a shorter measurement period without compromising the results.

For every individual drydown, we estimate λ and ET_0 by fitting a linear relation through the log-transformed ET observations of a single drydown effectively applying Equation 3. The method of least squares is used as fit criterion. With increasing R^2, the parameters converge until $R^2 \approx 0.3$ (not shown), which shows drydowns with a lower R^2 are less reliable. In addition, the parameters are required to be physically plausible meaning positive λ and ET_0, but below 35 days (maximum found by Teuling et al. (2006)) respectively 10 $\mathrm{mm\,d^{-1}}$. Also, the average temperature during a drydown needs to exceed 0°C to exclude snow conditions, which is strict enough, confirmed by a check against snow records. To quantify the uncertainty of the estimated parameters, we applied bootstrapping using 5000 re-samples containing 90% of the estimates. The confidence interval is defined as the 5^{th} and 95^{th} percentile of the median distribution from the re-samples.

With λ and ET_0 the storage capacity is calculated according to Equation 4 (shaded area in Figure 1), as we assume the storage to be completely filled after every rainfall event. This assumption is supported by the absence of dependence of the parameters to the rainfall before the drydown. Drydowns from all seasons are included and analyzed for a seasonal effect, since the water storage available to the atmosphere may change due to for example leaf phenology. Since it is not feasible to measure the water storage capacity in a complete urban footprint, this methodology offers the most direct estimation of the urban water storage. To investigate the possible impact of day-to-day variation

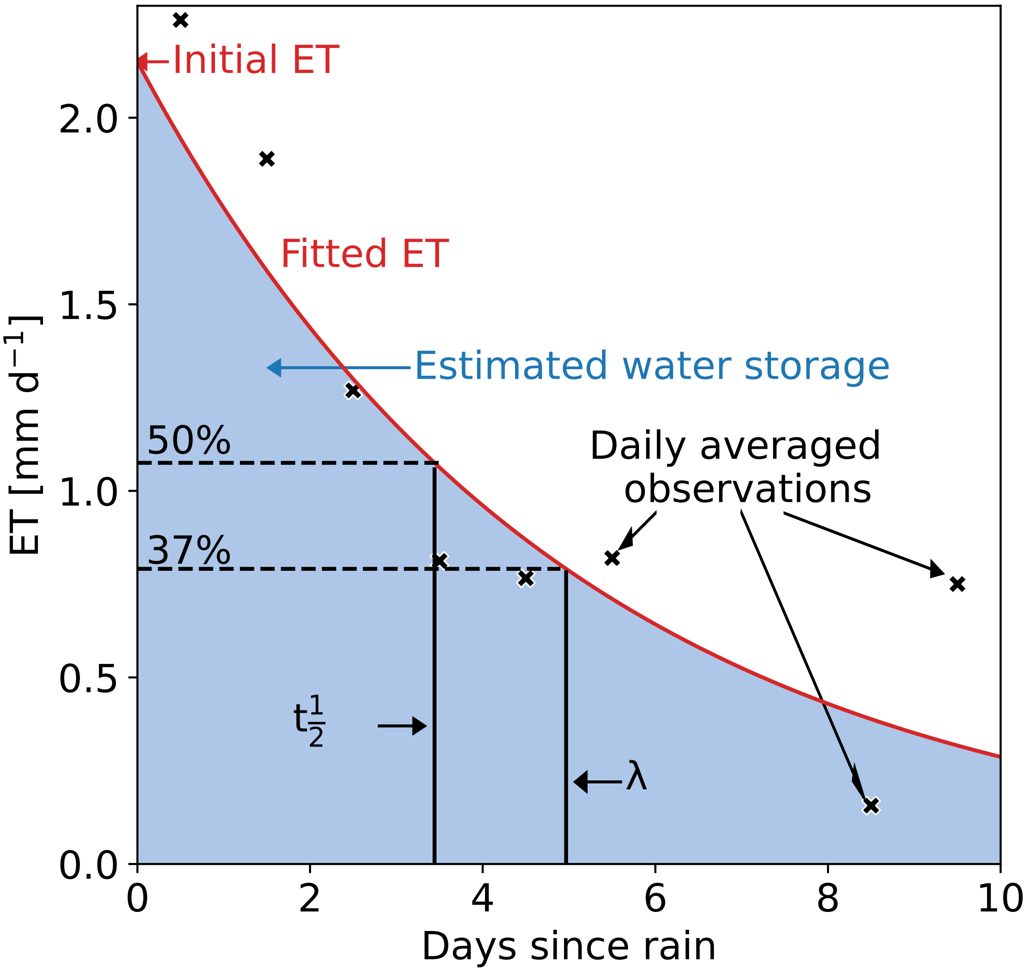

Figure 1. Illustration of the recession analysis. 24-hour aggregated ET versus the number of days following the last hour of precipitation for an example drydown from the Seoul data set with the fitted recession curve. Note that the fit was obtained by a linear fit on log-transformed data (see Data and Methods). In the figure the parameters are indicated.

or change in energy availability on the results, we repeated the recession analysis based on evaporative fraction (Gentine et al., 2007) multiplied by the average available energy over the drydown, which we included in the supplementary information (Table S1 and Figure S1 and S2).

3 Results

In Figure 2, the individual drydowns (in grey) show a good resemblance of the characteristic behaviour of the recession confirming the exponential behaviour. In general, ET is quickly decaying within days after rainfall in all LCZ's represented in our sample, indicating urban ET is generally strongly limited by water availability even on the first day after rainfall. As all cities respond approximately similarly, this confirms the qualitative, decaying relation during a drydown. The spread of the observations is higher than the uncertainty, which is the result of a seasonal dependency. The uncertainty is visibly higher in cities with shorter measurement periods, since shorter periods inevitably mean smaller samples of drydowns. For Arnhem, Basel (both), Berlin (both), Helsinki, Łódź and Vancouver, observations are available for more than two full years resulting in narrow uncertainty bands. In contrast to the uncertainty bands for the sites with records of less than two years (Amsterdam, Melbourne, Mexico City, Seoul and Singapore), which are as wide as the range of observations. In some panels (e.g. Amsterdam and Helsinki), we observe two groups of curves with distinct slopes, for which we found no explanation in seasonality, energy availability, temperature and pre-drydown rainfall (amount and timing).

In Table 1, an overview of the parameters is given for the 583 drydowns that complied with all criteria. Of the total number of 1606 drydowns, 540 are excluded because of a negative λ and 151 because of a λ above 35 days. All drydowns had a positive ET_0, and only three exceeded 10 $\mathrm{mm\,d^{-1}}$. Snow conditions potentially influenced 132 drydowns, which are thus excluded. Finally, 700 drydowns did not meet the minimum R^2 of 0.3. The remaining drydowns have an R^2 of 0.69 and yielded initial evapotranspiration between 0.3–2.1 $\mathrm{mm\,d^{-1}}$ and e-folding timescales between 1.8–20.1 days with the majority below 10.4 days, corresponding to half-lives of 1.3–14.0 and 7.2 days. The related storage capacities appear to be between 1.3–28.4 mm with the majority below 13.4 mm. As mentioned before, the length of the measurement period determines the magnitude of the uncertainty, which for S_0 varies from 1.2 mm in Basel (AESC) to 20.7 mm in Singapore.

For all sites, we find a considerable spread in the ET observations (Figure 2), which recurs in the estimated S_0 values. In Figure 3, S_0 is plotted against the month of the drydown, showing a very distinct seasonal dependency explaining why the spread in observations exceeds the uncertainty. Both ET_0 and λ, on which S_0 is based, show similar behaviour (not shown). Melbourne is shifted to fit the seasonality, as it is situated on the southern hemisphere. Since Singapore is close to the equator, it is not expected to show seasonal effect, which is confirmed in Figure 3. We expect that the effective storage capacity in summer is caused by increased root activity. Any connection between S_0 and the site characteristics in Table 1 and climatic variables among which precipitation regime is overshadowed by the seasonal dependency covering the full range of S_0 (Table 1), as we illustrate in Figure S3 and S4. It is unfortunately not possible to eliminate the influence of this dependency by focusing on one season due to the steep slope, and not by focusing on one month due to the low data density. Only after omitting half of the cities based on the number of drydowns, a relation between S_0 and site characteristics is visible (Figure S5).

4 Discussion

In contrast to the results presented here for urban areas, Teuling et al. (2006) found timescales ranging from 15–35 days and storage varying between 30 and 150 mm for forests and grassland following a similar methodology. When compared to the urban parameter values (1.8–20.1 days and 1.3–28.4 mm), it is clear that both the timescales and storage capacities are much higher in rural areas. McColl et al. (2017) have analyzed soil moisture drydowns in a global study using satellite data with a resolution too coarse to explicitly resolve individual cities, thus resembling rural values. Although their timescales with values from 2–20 days are closer to ours, it must be noted the temporal resolution is one in every three days and their observations only regard the first few centimeters instead of the root zone. Also, the satellite product in their research is known to underestimate the timescales compared to in-situ observations (Rondinelli et al., 2015; Shellito et al., 2016). When compared to storage values found for impervious surfaces by Wouters et al. (2015) (1.1–1.5 mm), the values in this study are higher as a result of the footprint scale analysis that includes natural in addition to impervious surfaces. Hence, the results show that both λ and S_0 are an order of magnitude smaller in cities indicating shorter

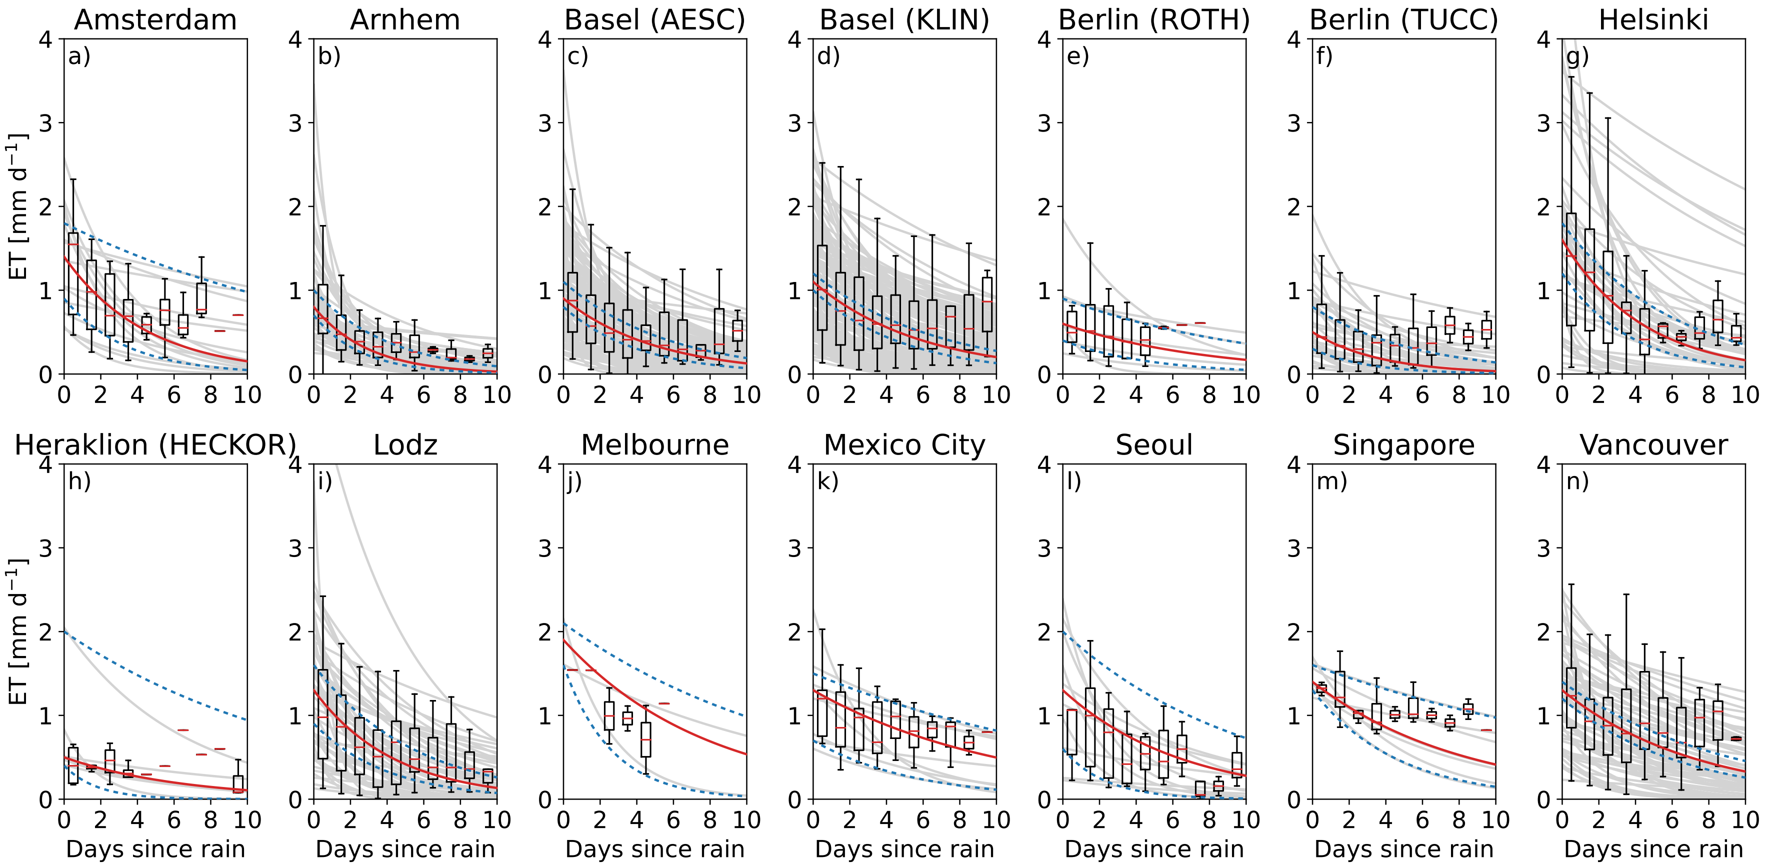

Figure 2. Daily average ET versus the day since the last precipitation with in red (continuous) the recession curve using the median parameter values, in blue (dotted) the 5^{th} and 95^{th} percentile of the median distribution from the bootstrapping re-samples, and in light grey all individual drydowns. The boxplots show the spread of the observations. The parameters of the fitted curves are shown in Table 1
. Since the parameters are based on individual drydowns, they do not necessarily follow the trend of the distributions.

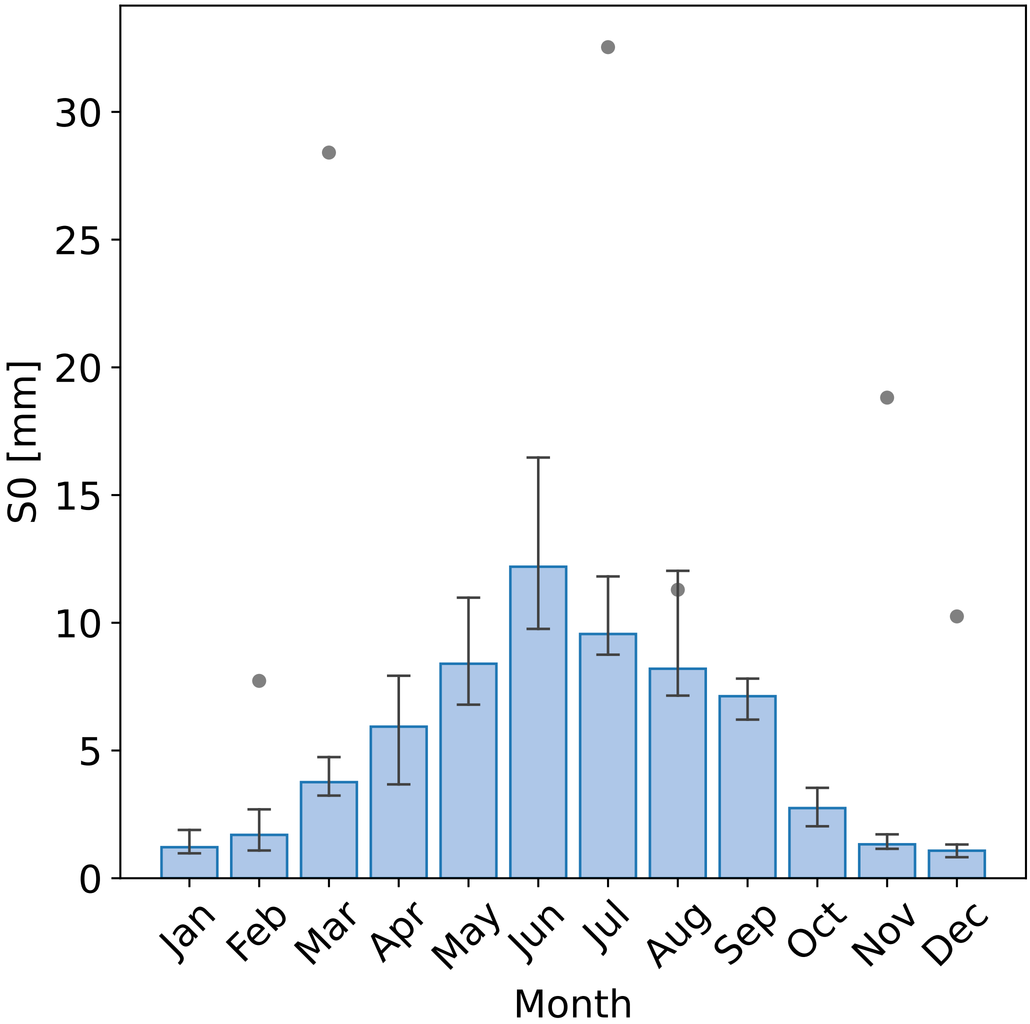

Figure 3. The seasonal dependency of the median S_0 for the sites on the northern hemisphere (Melbourne is included shifted by half a year) in blue and for Singapore as grey dots. The uncertainty is determined similarly as in Figure 2.

timescales and lower storage capacities in urban areas regardless of their climate and vegetation fraction.

Since our method is based on direct inference from observations, the reliability of the measurements determines the quality of our estimates. Eddy covariance is a sophisticated method for measuring fluxes, but comes with a set of potential challenges in cities (Velasco & Roth, 2010; Feigenwinter et al., 2012; Järvi et al., 2018). By carefully selecting locations and applying quality control, these problems are minimized. All sites have an observation height well above the mean building height (see Table 1), and measure in the inertial sublayer. This reduces the variability in flux measurements in response to the heterogeneity of the monitored footprint, which is induced by the many, unevenly distributed surfaces with different characteristics and water storage capacities in the urban landscape. The only site in this research that includes a non-homogeneous footprint is Seoul, for which the observations are filtered by wind direction to exclude a nearby forest. A relatively small variability between our estimates for each site suggest the observations are accurate enough for our application .

The methodology assumes that at the start of a drydown the storage capacity is completely full. A partly empty storage capacity would lead to an underestimation of the capacity, as less water is available for ET. We have compared the magnitude of the rain event before a drydown with the resulting parameters and found no correlation. Since the storage can be refilled by a series of events separated by dry days, we regressed the storage parameters against the Antecedent Precipitation Index (API) (Fedora & Beschta, 1989). The API takes into account rainfall occurring during preceding days (here limited to 20), but its observed values show no correlations with the λ and S_0. Therefore, the assumption of a completely filled storage is tangible and no selection has been performed based on rainfall event size. The evaporation directly after rainfall consists largely of interception ET from various surfaces (e.g. Grimmond & Oke, 1991; Gerrits, 2010; Oke et al., 2017). By calibrating an impervious-storage parameterization, (Wouters et al., 2015) estimated this storage to be between 1 and 1.5 mm for a site in Toulouse with little vegetation cover (8%), suggesting interception ET is an important component of urban ET also in more diverse and greener urban landscapes included in this study.

5 Conclusion

The timescales of ET recession observed through eddy covariance in urban environments appear to be considerably shorter than in rural environments. This is related to the storage capacity, which is also found to be lower. Based on 583 drydowns, we find recession timescales of cities within 1.8–20.1 days with the majority below 10.4 days and storage capacities between 1.3–28.4 mm with the majority below 13.4 mm. The timescales and storage capacities are inferred for the entire footprint (including all ET sources) and do not translate to impervious surfaces. Both are an order of magnitude smaller than found in rural areas. We were unable to analyze differences between cities to vegetation fraction, local climate zone or climate for two reasons. Firstly, the seasonal dependency in the storage capacities is as large as the total observed variation. Secondly, the number of sites is limited, and half of them contain data records shorter than one year. When provided with more data, the presented water storage capacity method has the potential to establish robust empirical relations explaining the differences between cities, in particular when complemented with soil moisture observations and/or Earth observation.
