## 14 **Abstract**

15 Fractures are frequently encountered in reservoirs used for geothermal heat extraction,  
 16 CO<sub>2</sub> storage, and other subsurface applications. Their significant impact on flow and trans-  
 17 port requires accurate characterisation for performance estimation and risk assessment.  
 18 However, fractures, and particularly their apertures, are usually associated with large  
 19 uncertainties. Data assimilation (or history matching) is a well-established tool for re-  
 20 ducing uncertainty and improving simulation results. In recent years, ensemble-based  
 21 methods like the ensemble smoother with multiple data assimilation (ESMDA) have gained  
 22 popularity. A key aspect of those methods is a well-constructed prior ensemble that ac-  
 23 curately reflects available knowledge. Here, we consider a geological scenario where frac-  
 24 ture opening is primarily created by shearing and assume a known fracture geometry.  
 25 Generating prior realisations of aperture with geomechanical simulators might become  
 26 computationally prohibitive, while purely stochastic approaches might not incorporate  
 27 all available geological knowledge. We therefore introduce the far-field stress approxi-  
 28 mation (FFSA), a proxy model in which this stress is projected onto the fracture planes  
 29 and shear displacement is approximated with linear elastic theory. We thereby compen-  
 30 sate for modelling errors by introducing additional uncertainty in the underlying model  
 31 parameters. The FFSA efficiently generates reasonable prior realisations at low compu-  
 32 tational costs. The resulting posterior ensemble obtained from our ESMDA framework  
 33 matches the flow and transport behaviour of the synthetic reference at measurement lo-  
 34 cations and improves the estimation of the fracture apertures. These results markedly  
 35 outperform those obtained from prior ensembles based on two naïve stochastic approaches,  
 36 thus underlining the importance of accurate prior modelling.

## 37 **Plain Language Summary**

38 Fractures are often present in subsurface reservoirs, but detecting and character-  
 39 ising them can be challenging. Understanding their location, size, and aperture (i.e., their  
 40 opening) is crucial for predicting heat production in geothermal reservoirs or prevent-  
 41 ing leaks during CO<sub>2</sub> storage. This study focuses on the fracture apertures as an unknown  
 42 quantity. We use ensemble-based data assimilation, which involves running numerous  
 43 simulations with varying parameter values, to get a more complete and accurate under-  
 44 standing of the system, particularly of the fracture apertures. We simulate tracer tests  
 45 (i.e., injecting fluid with a tracer into the reservoir) using different aperture values and  
 46 investigate how the initial guess for the aperture values impacts the results. Generat-  
 47 ing those initial aperture values with geomechanical simulations is accurate but can be  
 48 computationally expensive. As a fast and reasonably accurate alternative, we use the far-  
 49 field stress approximation (FFSA), which approximates the costly aspects of the geome-  
 50 chanical simulation. Initial guesses of the aperture values from FFSA outperform the ones  
 51 from naïve stochastic approaches in our framework, leading to better aperture estima-  
 52 tion at lower computational costs. This helps us to accurately model and predict the be-  
 53 haviour of fractures in subsurface reservoirs, contributing to more effective and reliable  
 54 energy and environmental solutions.

## 55 **1 Introduction**

56 Proper reservoir characterisation is crucial to accurately model flow and transport,  
 57 evaluate performance and assess risks in subsurface applications. These applications in-  
 58 clude geothermal energy extraction (Pruess, 2002; Kumagai et al., 2004; Häring et al.,  
 59 2008; Amann et al., 2018), geological carbon sequestration (Lu et al., 2013; Bui et al.,  
 60 2018; Shao et al., 2021), groundwater flow (Flury et al., 1994; Bear & Cheng, 2010), oil  
 61 and gas reservoirs (Parker, 1989; Ahr, 2008), and nuclear waste disposal (Tsang et al.,  
 62 2015). Many of these reservoirs contain pre-existing natural fractures or fractures cre-  
 63 ated during construction and operation, which can significantly impact flow and trans-

port (Matthäi & Belayneh, 2004; Geiger et al., 2004; Johnston et al., 2005; Geiger et al., 2010). The extent of their influence depends on fracture parameters such as length, orientation, apertures, location, connectivity, and density. As an example, highly conductive and interconnected fractures can serve as shortcuts for the flow, causing early breakthrough, while small and isolated fractures may have little effect on flow and transport. Precisely estimating these fracture parameters is thus essential.

However, direct measurement of fracture parameters is usually difficult. Several established techniques exist that detect and characterise fractures in the vicinity of boreholes, such as image logging, core analysis or spinner logs (Genter et al., 1997; Prensky, 1999; Al-Dhafeeri & Nasr-El-Din, 2007; Ali et al., 2021). However, boreholes are typically sparse and the space between them is not covered by those methods. Measuring seismic anisotropy on the other hand provides statistical or average information about fractures in the whole reservoir, but only the fracture orientation, density, and, to some extent, length distribution can be deduced, while the apertures and exact geometry of fractures remain unknown (E. Liu & Martinez, 2012). Outcrops show concrete realisations of the fracture geometry, albeit only at the earth’s surface. They serve as analogues from which statistical information about the fracture geometry in the subsurface reservoir can be inferred (Casini et al., 2016; Gutmanis et al., 2018). Geostatistical tools such as variograms and (co)kriging analyse and predict distributions of spatially correlated subsurface properties (Chilès & Delfiner, 2012). As a consequence, the fracture parameters, in particular the fracture apertures, are often subject to a high level of uncertainty.

It is therefore necessary to reduce the uncertainty in the fracture parameters for accurate flow and transport modelling in fractured reservoirs. Data assimilation (DA) or history matching is a common tool for reducing uncertainties in model parameters and subsequently improving simulation results by incorporating measurement data. In subsurface applications, often flow and transport measurements from well tests or dynamic production data are used. Popular DA methods include variational data assimilation based on the adjoint method, ensemble-based methods such as the ensemble Kalman filter (EnKF) or particle filter, and hybrid forms thereof (for a review see e.g. Asch et al., 2016; Bannister, 2017; Carrassi et al., 2018; Evensen et al., 2022). The EnKF, introduced by Evensen (1994), is an ensemble approximation of the original Kalman filter (Kalman, 1960) and does not require linearised or adjoint versions of the model or the observation operator. There exists a wide variety of EnKF versions, for a review see e.g. Houtekamer and Zhang (2016), Keller et al. (2018), or Evensen et al. (2022). While the classical EnKF updates the model parameter whenever new measurements are available, ensemble smoothers (ES) collect all measurements in space and time and perform updates only at the end of simulations (van Leeuwen & Evensen, 1996; Skjervheim et al., 2011). This simplifies the implementation as the reservoir simulator does not need to be interrupted. Iterative versions of the ES, such as the ensemble randomised maximum likelihood method (EnRML) (Chen & Oliver, 2012, 2013) or the ensemble smoother with multiple data assimilation (ESMDA) (A. A. Emerick & Reynolds, 2013), were developed for weakly to modestly non-linear systems and have gained popularity in recent years.

Several studies have applied DA to fracture apertures. Some studies assume an identical and known aperture value for all fractures and focus on reducing the uncertainty in other fracture parameters (Ping et al., 2017; Chai et al., 2018; Yao et al., 2018). However, it is known that fracture apertures vary considerably throughout the domain (C. A. Barton et al., 1995; Baghbanan & Jing, 2008; N. Barton & Quadros, 2015; X. Zhang et al., 2021). Other studies have used relatively simple, unconditional distributions to model the apertures (Zhe et al., 2016; Liem & Jenny, 2020; Q. Liu et al., 2022) or set them proportional to the fracture length (K. Zhang et al., 2021). However, these models may not accurately represent the complex relationship between aperture values and stress state, displacement history and fracture parameters such as orientation, length, and surface roughness. In Seabra et al. (2023), those complex relations are included, albeit without

117 shear displacement. They calculate fracture apertures as a function of effective normal  
 118 stress obtained from a geomechanical simulation and subsequently reduce the uncertainty  
 119 in the global model parameters with DA. In Wu et al. (2021), the authors follow an al-  
 120 together different approach and model aperture variations within the fracture plane of  
 121 a single fracture.

122 The performance of ensemble-based DA strongly depends on the quality of the prior  
 123 ensemble. In the above-mentioned studies, typically either the number of fractures is small  
 124 or when a moderate number of fractures is used, the apertures only depend on a few un-  
 125 derlying uncertain parameters. Ensemble-based DA usually performs well under such  
 126 conditions; however, it becomes more challenging when considering a large number of  
 127 fractures each with an individual aperture. The ensemble size is usually limited by com-  
 128 putational resources and therefore the prior distribution is likely undersampled. This re-  
 129 stricts the solution space as the posterior ensemble is a linear combination of the prior  
 130 ensemble (Evensen, 2003) and can lead to spurious correlations. Those issues are by no  
 131 means unique to DA in fractured reservoirs, but they arise in any other application where  
 132 a huge number of parameters is represented by a limited ensemble size, such as in me-  
 133 teorology, oceanography, or groundwater flows. A common strategy is to apply locali-  
 134 sation and inflation methods in the update step (e.g. Anderson & Anderson, 1999; Houtekamer  
 135 & Mitchell, 2001; Chen & Oliver, 2010; A. Emerick & Reynolds, 2011; Luo & Bhakta,  
 136 2020; Evensen et al., 2022).

137 In this work, we pursue a different (and possibly complementary) approach to im-  
 138 proving the prior ensemble by incorporating additional physical knowledge. We thereby  
 139 consider a situation where the fracture apertures are predominantly created by shear-  
 140 ing driven by the tectonic far-field stresses. Toolkits with geomechanical capabilities such  
 141 as ABAQUS (Smith, 2009; Agheshlui et al., 2018), COMSOL (Multiphysics, 2013), DARTS  
 142 (Y. Wang et al., 2020; Boersma et al., 2021), ICGT (Thomas et al., 2020; Paluszny et  
 143 al., 2020), MRST (Ucar et al., 2018; Lie & Møyner, 2021), OpenCSMP (Pezzulli et al.,  
 144 2022a, 2022b), or XFVM (Deb & Jenny, 2017a, 2017b) can be used to calculate shear  
 145 displacement and fracture apertures for this scenario. However, it might be computa-  
 146 tionally expensive to generate a whole ensemble of realisations that are needed as pri-  
 147 ors for a DA framework, especially when considering a decent number of fractures. A  
 148 purely stochastic approach on the other hand is unlikely to include all available phys-  
 149 ical knowledge and cannot represent the complex relationship between apertures and other  
 150 modal parameters.

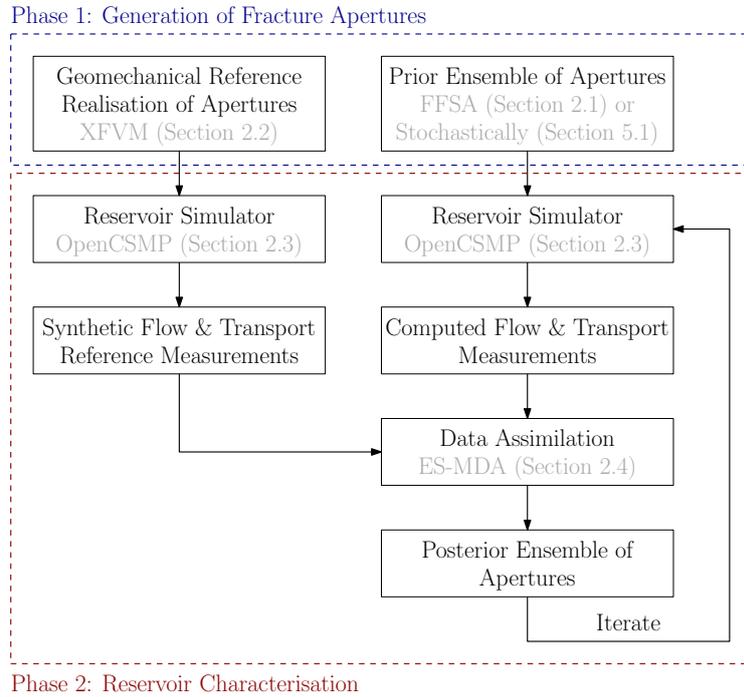

151 We therefore look for a method that produces physically meaningful prior realisa-  
 152 tions at little computational cost. For this, we build upon existing proxy models (Milliotte  
 153 et al., 2018; Agheshlui et al., 2019; J. Wang et al., 2023) and propose a method based  
 154 on far-field stress approximation (FFSA). FFSA projects the tectonic far-field stresses  
 155 onto the fracture planes and estimates the shear displacements based on linear elastic  
 156 theory. Thus, we do not need to solve differential equations, which makes the method  
 157 computationally attractive. We account for the errors introduced by those approxima-  
 158 tions by additional uncertainty in a model parameter. We combine the FFSA with the  
 159 constitutive relations of Barton and Bandis (N. Barton & Choubey, 1977; N. Barton, 1982;  
 160 Bandis et al., 1983; N. Barton et al., 1985; Lei & Barton, 2022) and integrate it into our  
 161 ESMDA framework. We use flow and transport data to improve the estimation of the  
 162 fracture apertures. While a preliminary version of this approach has already been pub-  
 163 lished (Liem et al., 2022), this work refines and extends the method and presents more  
 164 extensive and impactful results. In particular, we obtain the synthetic reference flow and  
 165 transport data from a realisation generated with a geomechanical reservoir simulator,  
 166 and we compare the performance of our DA framework when using prior ensembles gen-  
 167 erated with the FFSA to two stochastically generated prior ensembles.

168 This paper is organised as follows: Section 2 introduces our data assimilation frame-  
 169 work including the FFSA for generating prior ensembles. In Section 3, we discuss the

170 fracture geometry, and in Section 4, the model parameters, some of which are assumed  
 171 to be uncertain. The results of this study, which are presented in Section 5 and discussed  
 172 in depth in Section 6, show that reasonable prior ensemble realisations can be obtained  
 173 with FFSA. Ensembles generated with FFSA outperform the ones from two naïve stochastic  
 174 approaches in our DA framework.

## 175 2 Method

176 In this work, we consider a geological scenario that consists of two phases. In Phase 1,  
 177 the fracture apertures are generated. We study a thin layer of fractured rock embedded  
 178 between two impermeable and rigid layers. All fractures are present from the beginning,  
 179 and we do not consider any fracture propagation. The fractures are initially closed and  
 180 there is no history of tectonic folding, uplifting, or cooling. We apply a tectonic far-field  
 181 stress and steadily increase the fluid pressure within the fractures. As the effective normal  
 182 stress decreases, some fractures begin to slip and consequently dilate due to asperities  
 183 on the fracture surface. As a result, the apertures vary considerably from fracture  
 184 to fracture. Due to numerous sources of uncertainty, e.g. in the stress state, rock prop-  
 185 erties or fracture roughness, the fracture apertures cannot be calculated deterministi-  
 186 cally but are also associated with some uncertainty. In Phase 2, we perform a tracer test  
 187 to characterise the reservoir, while we assume that the fluid injection does not affect the  
 188 fracture apertures. We use an iterative ensemble-based data assimilation (DA) frame-  
 189 work (Figure 1) to history match the fracture apertures and obtain a posterior aperture  
 190 estimate with reduced uncertainty. In the following, the individual building blocks of the  
 191 DA framework are explained in detail.

**Figure 1.** Iterative data assimilation framework used in this work

192  
193

## 2.1 Prior Ensemble of Apertures with Far-Field Stress Approximation (FFSA)

194  
195  
196  
197

Here, we present a simple and fast method for estimating fracture apertures that can be used to generate a reasonable prior ensemble with little computational cost. We approximate the stress state at the fractures from the far-field stress using Cauchy's equations

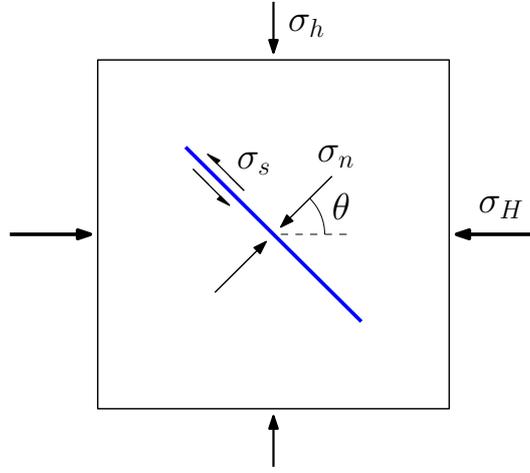

198  
199  
200

$$\sigma_n = \sigma_H \cos^2 \theta + \sigma_h \sin^2 \theta \quad \text{and} \quad (1)$$

$$\sigma_s = (\sigma_h - \sigma_H) \sin \theta \cos \theta \quad , \quad (2)$$

201  
202  
203  
204  
205  
206

where  $\sigma_H$  and  $\sigma_h$  are the maximum and minimum principal horizontal stresses and  $\theta$  is the angle between  $\sigma_H$  and the fracture normal (Figure 2). Those equations are only valid for a virtual plane in an intact material, as is the case when all fractures are closed and shear stress is fully transmitted over the fractures. They ignore fracture interactions and hence only provide approximate solutions when shear displacement or tensile opening occurs in other fractures.

**Figure 2.** Projection of principal horizontal far-field stresses,  $\sigma_H$  and  $\sigma_h$ , onto a fracture

207  
208

A fracture begins to slip when shear stress exceeds shear strength, i.e. when  $|\sigma_s| > \tau_{max}$ . The shear strength according to Coulomb's friction law is

209

$$\tau_{max} = \begin{cases} \sigma_{eff} \cdot \tan(\phi'), & \sigma_{eff} > 0 \\ 0, & \text{otherwise,} \end{cases} \quad (3)$$

210  
211

where  $\sigma_{eff} = \sigma_n - p_f$  is the effective normal stress,  $\phi'$  the friction angle, and  $p_f$  the fluid pressure. As the fracture slips, the shear stress relaxes until the arrest criterium

212

$$|\sigma_s| \leq \tau_{max} \quad (4)$$

213  
214  
215

is satisfied. We approximate the decrease  $\Delta\sigma_s$  in shear stress for an increment  $\Delta\delta_s$  of shear displacement with linear elastic theory (Eshelby & Peierls, 1957; Chinnery, 1969; Willis-Richards et al., 1996; Rahman et al., 2002), i.e., we assume

216

$$\frac{\Delta\sigma_s}{G} = C_g \frac{\Delta\delta_s}{L} \quad , \quad (5)$$

217  
218

where  $G$  is the shear modulus of the surrounding material,  $L$  the fracture length and  $C_g$  a proportionality factor. This then allows us to calculate the total shear displacement

219  $\delta_s$  of a fracture. The amount of shear dilation  $\delta_d$  is then obtained by integrating the tan-  
 220 gent of the dilation angle  $\phi_d$  over shear displacement, i.e.,

$$221 \quad d\delta_d = d\delta_s \tan(\phi_d) \quad \rightarrow \quad \delta_d = \int_0^{\delta_s} \tan(\phi_d) d\delta_s . \quad (6)$$

222 In this work, we use the constitutive model of Barton and Bandis (N. Barton & Choubey,  
 223 1977; N. Barton, 1982; Bandis et al., 1983; N. Barton et al., 1985; Lei & Barton, 2022)  
 224 to calculate friction and dilation angles (Appendix A1). In this empirical model, these  
 225 angles are algebraic functions of the shear displacement. They reach a peak value for a  
 226 certain shear displacement and then decrease for larger displacements. Thus, Equations (3)  
 227 to (5) form a non-linear system of equations. The fracture aperture

$$228 \quad a = a_0 - \delta_n + \delta_d \quad (7)$$

229 is a combination of an initial fracture aperture  $a_0$ , closure due to normal stress  $\delta_n$  and  
 230 shear dilation  $\delta_d$ . In this work, we do not consider tensile opening and set the hydraulic  
 231 aperture equal to the mechanical aperture.

## 2.2 Geomechanical Reference Realisation of Apertures with XFVM

232  
 233 To generate an accurate reference of the aperture field, we need a proper geome-  
 234 chanical simulator. To this end, we employ an implementation of the extended finite vol-  
 235 ume method (XFVM), an embedded discrete fracture method that includes lower-dimensional  
 236 fracture manifolds in Cartesian grids (Deb & Jenny, 2017a, 2017b). In 2D, each fracture  
 237 is divided into line segments, where each segment has one degree of freedom for shear  
 238 slip, resulting in piecewise constant displacements along the fractures. Linear elasticity  
 239 of the rock is assumed, the force balance is solved in an integral manner, and we use Coulomb's  
 240 friction law (Equation (3)) as a slip criterion. The displacement field is approximated  
 241 by continuous basis functions at the grid points and discontinuous basis functions to rep-  
 242 resent fracture manifolds. These special discontinuous basis functions ensure that the  
 243 displacement gradient is continuous across the manifold, allowing the calculation of shear  
 244 stress on the fracture without additional constraints. We then solve the system of lin-  
 245 ear equations for the displacement at the grid points and the shear slip of the segments.  
 246 As in our approach with FFSA, we calculate shear dilation with the constitutive model  
 247 of Barton and Bandis described in Appendix A1. To this end, we adjust the dilation an-  
 248 gle  $\phi_d$  at each time step to account for changes in roughness while the shear dilation is  
 249 coupled to the stresses and hence accounted for in the force balance, as described in Conti  
 250 et al. (2023). The fracture aperture of each segment is obtained from Equation (7), where  
 251 the initial aperture and normal closure are added in a post-processing step.

## 2.3 Flow and Transport Computation based on OpenCSMP

252  
 253 As a reservoir simulator, we use the Complex Systems Modelling Platform (OpenC-  
 254 SMP) (Geiger et al., 2004; Matthäi et al., 2007), a finite element – finite volume frame-  
 255 work. It offers a wide range of functionality to calculate flow and transport processes with  
 256 a focus on fractured porous media. In this work, we consider tracer transport by a steady-  
 257 state velocity field. We calculate the volumetric flow field  $\mathbf{q}$  of a single-phase fluid with  
 258 dynamic viscosity  $\mu$  through a porous medium with permeability  $k$  from Darcy's law

$$259 \quad \mathbf{q} = -\frac{k}{\mu} \nabla p \quad (8)$$

260 and the continuity equation  $\nabla \cdot \mathbf{q} = \dot{q}_{\text{source}}$ , which can be combined and result in the  
 261 elliptic pressure equation

$$262 \quad \nabla \cdot \left( \frac{k}{\mu} \nabla p \right) + \dot{q}_{\text{source}} = 0 . \quad (9)$$

263 Here,  $p$  is the steady-state pressure and  $\dot{q}_{\text{source}}$  is the source term which is positive for  
 264 fluid injection and negative for extraction. At time  $t_0$ , we start injecting a passive tracer  
 265 which follows the flow field perfectly. The tracer does not alter the flow field and we ne-  
 266 glect diffusion. We calculate the evolution of this tracer with the hyperbolic scalar trans-  
 267 port equation

$$268 \quad \phi \frac{\partial c}{\partial t} + \mathbf{q} \cdot \nabla c - \dot{q}_{\text{source}} c_{\text{source}} = 0, \quad (10)$$

269 where  $c$  is the tracer concentration and  $\phi$  the porosity. We solve tracer transport with  
 270 a first-order version of discrete event simulation (DES) (Shao et al., 2019), a totally asyn-  
 271 chronous local time stepping scheme.

## 272 2.4 Data Assimilation with ESMDA

273 In this work, we use the ensemble smoother with multiple data assimilation (ES-  
 274 MDA) proposed by A. A. Emerick and Reynolds (2013). As an ensemble smoother, the  
 275 ESMDA collects all measurements in time and space in one vector and performs a Kalman  
 276 update once the reservoir simulation is completed. The ESMDA alternately performs  
 277 update steps with the same reference measurements and reruns the reservoir simulator  
 278 with the updated parameters (Figure 1). Those iterations are necessary due to the non-  
 279 linear reservoir simulator.

280 We create a prior ensemble  $x_{1:N_E}^{\text{prior}}$  of  $N_E$  realisations with FFSA and one reference  
 281 realisation  $x^{\text{ref}}$  with XFVM. In this work, the parameter vector of a certain realisation  
 282  $i$ ,

$$283 \quad x_i = [\log_{10}(a_1^i), \log_{10}(a_2^i), \dots, \log_{10}(a_N^i)]^T, \quad (11)$$

284 contains the logarithms of the aperture values of all  $N$  fractures. We run a reservoir sim-  
 285 ulator developed on the basis of OpenCSMP for each realisation to obtain the correspond-  
 286 ing measurement vector  $y_i$ , which consists of pressure values, volume flow rates and tracer  
 287 arrival times.

288 We then get an updated posterior estimation of the fracture apertures with reduced  
 289 uncertainty by combining the prior knowledge about the model parameter with the un-  
 290 certainty in the measurements. We thereby integrate the stochastic EnKF of Algorithm  
 291 6.3 in Asch et al. (2016) into the ESMDA as described in Liem et al. (2022). The up-  
 292 date or analysis step of a standard stochastic EnKF is

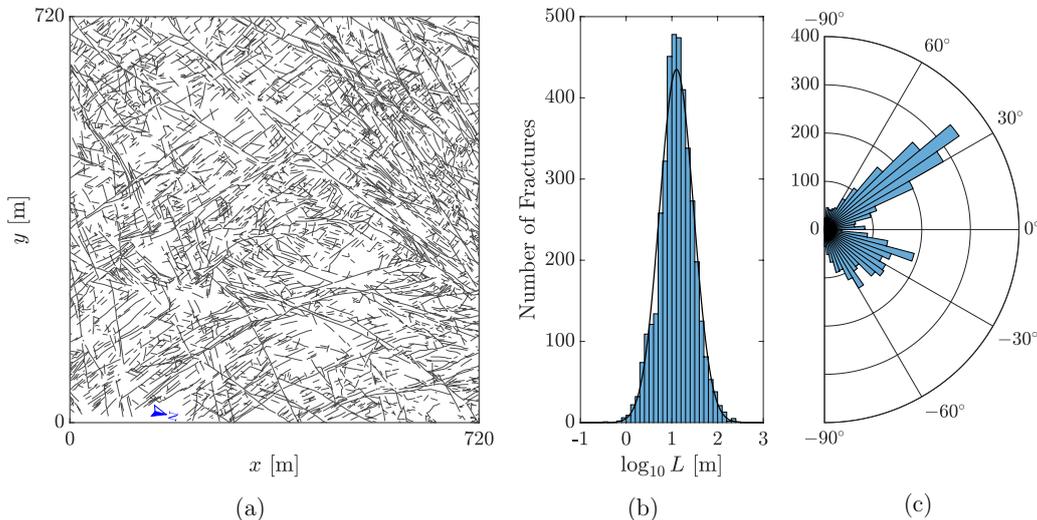

$$293 \quad x_i^a = x_i^f + K (y^{\text{ref}} - (y_i + u_i)) \quad \text{with } u_i \sim \mathcal{N}(0, R), \quad (12)$$

294 where the superscripts  $f$  and  $a$  denote parameter vectors before and after the update  
 295 step and the sets of all  $x_i^f$  and  $x_i^a$  are called prior and posterior ensembles, respectively.  
 296  $R$  is the measurement error covariance matrix and following van Leeuwen (2020) we ap-  
 297 ply the perturbations  $u_i$  to the ensemble measurements. In order to ensure consistency,  
 298 the measurement error covariance matrix must be inflated accordingly. This and the cal-  
 299 culation of the Kalman gain  $K$  are explained in Appendix A2.

## 300 3 Fracture Geometry

301 This study uses a realistic fracture geometry with  $N = 4051$  individual fractures  
 302 (Figure 3a) identical to the one in Liem et al. (2022), except for minor changes in the  
 303 classification of segments into individual fractures. The geometry was mapped by Odling  
 304 (1997) from aerial photography of the Hornelen basin in western Norway. The mapped  
 305 region extends over an area of  $720 \times 720$  m, with aerial photos taken from a height of  
 306 370 m. The smallest observable features were 30 cm wide depressions filled with soil, grass  
 307 or water. More fractures became visible at smaller observation heights; thus, the geom-  
 308 etry shown in Figure 3a represents merely a subset of the total fractures present.

309 The fracture geometry has approximately a log-normal distribution of fracture length  
 310 (Figure 3b) and a bi-modal distribution of fracture orientation with the most prominent  
 311 peak at around  $40^\circ$  (Figure 3c). The Hornelen basin is filled with fractured Devonian-  
 312 age Old Red Sandstone (e.g. Torsvik et al., 1988) with a very low permeability. The frac-  
 313 ture apertures observed at the surface are not representative of the ones at reservoir depth,  
 314 as stress conditions are markedly different. Therefore, we rely on a geomechanical sim-  
 315 ulator to calculate the reference apertures.

**Figure 3.** Fracture trace map of Hornelen basin outcrop (a) and histogram of logarithm of fracture length (b) and fracture orientation (c). The line in (b) shows a log-normal distribution with same mean and standard deviation. The fracture geometry was mapped by Odling (1997) and digitalised and discretised by Azizmohammadi and Matthäi (2017). Figure adapted from Liem et al. (2022).

## 316 4 Simulation Setup

317 The thin horizontal layer of fractured rock is embedded between two rigid and im-  
 318 permeable layers with fractures perpendicular to bedding. These assumptions enable us  
 319 to approximate the model as 2D. We approximate the fractures by straight lines for the  
 320 mechanical simulations (i.e. XFVM and FFSA). For the XFVM reference, we use a grid  
 321 spacing of 2 m, resulting in roughly 46000 fracture segments.

### 322 4.1 Uncertain Model Parameters

323 While we assume that we know the fracture geometry exactly, other geomechanical  
 324 model parameters of Phase 1 are associated with some uncertainty (Table 1). We  
 325 distinguish parameters that are equal for all fractures within one realisation and sam-  
 326 pled therefore only once per realisation (indicated with target 'R') and parameters that  
 327 are different for each fracture within each realisation (target 'F'). Consequently, the to-  
 328 tal number of sampled model parameters per realisation is  $8+5N = 20263$ . In the fol-  
 329 lowing, we discuss the parameters and their uncertainty in more detail.

330 We model a burial depth of the fractured reservoir of 1500 m, corresponding to an  
 331 overburden stress  $\sigma_v$  of approximately 32 MPa based on an average rock density of around  
 332  $2.2 \text{ g/cm}^3$ . We assume a normal faulting regime (i.e.  $\sigma_v > \sigma_H > \sigma_h$ ) and set the min-

**Table 1.** Uncertain geomechanical model parameters. We use scaled beta distributions defined by mean  $\mu$ , standard deviation  $\sigma$  and [upper bound, lower bound]. For generating the prior ensemble with FFSA, we sample parameters with target 'R' only once per realisation and those with target 'F' for every fracture individually. The last column lists the input parameters for the reference simulation with XFVM.

Symbol	Unit	$\mu$	$\sigma$	Bounds	Target	Ref
$\beta$	degree	0	5	[-15, 15]	R	0
$\sigma_H$	MPa	30	0.6	[28, 32]	R	29.7
$\sigma_h$	MPa	23	0.3	[22, 24]	R	23.3
$p_f$	MPa	21.5	0.15	[21, 22]	R	21.8
$\phi_r$	degree	25	1	[22, 28]	R	25
$\sigma_c$	MPa	70	3	[61, 79]	R	70
$E$	MPa	5000	500	[3500, 6500]	R	5000
$\nu$	–	0.25	0.0075	[0.2275, 0.2725]	R	0.25
$JRC_{small}$	–	6	1	[2, 10]	F	sampled
$JRC_{large}$	–	2	0.6	[0, 4]	F	sampled
$K_{ni}$	$\frac{\text{MPa}}{\text{mm}}$	20	5	[10, 30]	F	sampled
$v_m^{rel}$	–	0.5	0.125	[0.25, 0.75]	F	sampled
$C_g$	–	1	0.1	[0.7, 1.3]	F	–

333 imal principal horizontal stress to  $\sigma_h \approx 0.7\sigma_v$ . The orientation  $\beta$  of the maximum principal  
 334 principal horizontal stress  $\sigma_H$  is described in Heidbach et al. (2018); here, we roughly align  
 335 it to the  $x$ -axis of our coordinate system. We assume a constant fluid pressure  $p_f$  across  
 336 the entire field. We choose a fluid pressure close to  $\sigma_h$  to get a reasonable amount of shear-  
 337 ing but ensure that it remains smaller than  $\sigma_h$  to prevent tensile opening. Although the  
 338 material properties of the rock (here Young's modulus  $E$ , Poisson's ratio  $\nu$ , shear modulus  
 339  $G = \frac{E}{2(1+\nu)}$ , unconfined compressive strength  $\sigma_c$ , and residual friction angle  $\phi_r$ )  
 340 are rarely uniform in a reservoir, we approximate them as such. The chosen values are  
 341 loosely inspired by Ojo and Brook (1990) and Hawkins and McConnell (1991).

342 The friction of the fracture planes plays a crucial role and represents a significant  
 343 source of uncertainty. Two parameters describe friction in our constitutive model (Ap-  
 344 pendix A1). The residual friction angle  $\phi_r$  is a material property and describes friction  
 345 of a planar rock surface. The joint roughness coefficient  $JRC$ , on the other hand, de-  
 346 scribes the increase of friction due to surface roughness which differs from fracture to frac-  
 347 ture. In this work, we consider surface roughness at two different length scales: small-  
 348 scale roughness at the level of the asperities (e.g. Pollard & Aydin, 1988) as described  
 349 by the original Barton and Bandis model and modelled here with  $JRC_{small}$ , and an ad-  
 350 ditional roughness compensating for idealising fractures as straight lines in our model.  
 351 We calculate the combined joint roughness coefficient as

$$352 \quad JRC = JRC_{small} + JRC_{large} \cdot \log_{10}(L), \quad (13)$$

353 where the fracture length  $L$  is in meters.

354 Additional fracture parameters in the Barton and Bandis model (Appendix A1)  
 355 include the initial normal stiffness  $K_{ni}$  and the maximum possible closure  $v_m = v_m^{rel} a_0$ .  
 356 While the FFSA provides accurate results for a single fracture, it does not account for  
 357 interactions between fractures (Appendix A3). To address the limitations of this approx-  
 358 imation, we introduce additional uncertainty through the proportionality coefficient  $C_g$   
 359 that relates shear stress to shear displacement.

360 The amount of shear displacement and consequently also fracture aperture obtained  
 361 from FFSA corresponds to the maximum value along the fracture length. In the friction-  
 362 less case, shear displacement follows an elliptic profile (Eshelby & Peierls, 1957). Due  
 363 to the non-linear constitutive model of Barton and Bandis, the profiles of shear displace-  
 364 ment and aperture are only approximately elliptic. Those profiles can have in general  
 365 arbitrary shapes in the XFVM. For simplicity, however, we assume a constant aperture  
 366 over the length of a fracture and assign it to the maximum aperture value.

367 Ideally, we would compare the FFSA prior to a prior ensemble generated from XFVM.  
 368 However, this is computationally too expensive. We therefore compare it to prior ensem-  
 369 bles from two naïve stochastic approaches. They both sample from the unconditional prob-  
 370 ability density function (PDF) of the FFSA prior.

## 371 4.2 Parameters for Flow and Transport Simulation and ESMDA Up- 372 dates

373 In Phase 2 of the geological scenario, we alternately perform tracer tests and up-  
 374 date the fracture apertures with ESMDA. For the tracer test, we inject fluid through a  
 375 single fracture named 'well fracture', which is located at the centre of the domain, and  
 376 apply a constant pressure at all four boundaries (Figure 4a). Starting at time  $t_0 = 0$ ,  
 377 a scalar tracer with concentration  $c = 1$  is introduced into the injected fluid. We com-  
 378 pute the steady-state velocity field and tracer transport using OpenCSMP (Section 2.3).  
 379 The matrix domain is thereby discretised with an unstructured triangular mesh, and the  
 380 fractures are represented as lower-dimensional line elements (Azizmohammadi & Matthäi,  
 381 2017). In this work, we decouple flow and transport from the fracture mechanics, assum-  
 382 ing that fluid injection does not affect the fracture apertures. While this assumption is  
 383 often invalid in real-world scenarios, it is necessary in our framework due to computa-  
 384 tional limitations. The relevant parameters for the flow and transport simulations are  
 385 provided in Table 2. Note that we calculate the fracture permeabilities from the frac-  
 386 ture apertures assuming plane Poiseuille flow between two parallel plates.

**Table 2.** Parameters for flow and transport simulation with OpenCSMP

Fluid viscosity	$\mu$	$1 \times 10^{-3}$ Pa s
Matrix permeability	$k_m$	$3 \times 10^{-13}$ m <sup>2</sup>
Matrix porosity	$\phi_m$	0.15
Fracture permeability	$k_f$	$a^2/12$
Fracture porosity	$\phi_f$	1.0
Pressure at all 4 boundaries	$p_{out}$	9 MPa
Inlet volume flow	$\dot{Q}_{in}/l_w$	$2 \times 10^{-3}$ m <sup>2</sup> /s
Length of well fracture	$l_w$	56.48 m
<i>CFL</i> multiplier for DES		0.4

387 In this work, we assume that measurements along the domain boundary and in the  
 388 well fracture are available (Figure 4b). Concretely, we measure the maximum value of  
 389 the steady-state pressure  $p_{in}$  along the well fracture and the volume flow rate  $\dot{Q}_{out}$  through  
 390 20 model-boundary segments. Further, we monitor the evolution of the tracer concen-

391 tration at certain locations on the boundary and either use the concentration value af-  
 392 ter 320 days,  $c_{320}$ , or the time it takes to reach a concentration of 0.5,  $t_{0.5}$ , as measure-  
 393 ments. The number of measurements and their locations are arbitrary choices. To evalu-  
 394 ate the performance of the DA framework, we set 12 measurements (indicated in yel-  
 395 low in Figure 4b) aside and use the remaining 60 measurements for the ESMDA updates.  
 396 We call them test and training measurements, respectively. We scale the measurements  
 397 as

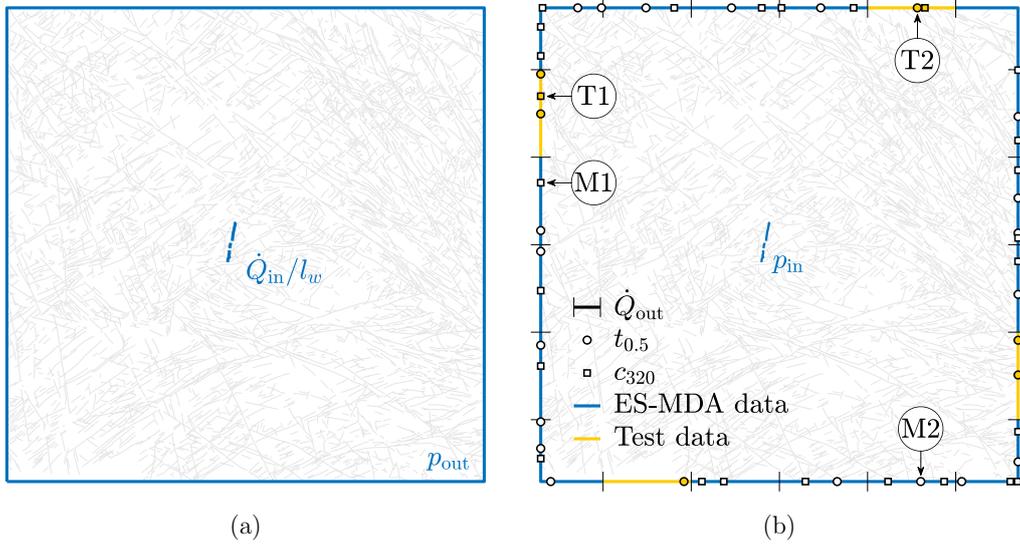

$$398 \quad \tilde{p}_{\text{in}} = \frac{p_{\text{in}} - p_{\text{out}}}{p_{\text{out}}} \quad , \quad \tilde{Q}_{\text{out}}^{(i)} = \frac{\dot{Q}_{\text{out}}^{(i)}}{\dot{Q}_{\text{in}}/20} \quad , \quad \tilde{t}_{0.5}^{(i)} = \frac{t_{0.5}^{(i)}}{640 \text{ days}} \quad , \quad \tilde{c}_{320}^{(i)} = c_{320}^{(i)} \quad (14)$$

399 and collect them in the training and test measurement vectors

$$400 \quad y = \left[ \tilde{p}_{\text{in}}, \tilde{Q}_{\text{out}}^{(1)}, \dots, \tilde{Q}_{\text{out}}^{(16)}, \tilde{t}_{0.5}^{(1)}, \dots, \tilde{t}_{0.5}^{(19)}, \tilde{c}_{320}^{(1)}, \dots, \tilde{c}_{320}^{(24)} \right]^T \quad \text{and} \quad (15)$$

$$401 \quad z = \left[ \tilde{Q}_{\text{out}}^{(17)}, \dots, \tilde{Q}_{\text{out}}^{(20)}, \tilde{t}_{0.5}^{(20)}, \dots, \tilde{t}_{0.5}^{(25)}, \tilde{c}_{320}^{(25)}, \dots, \tilde{c}_{320}^{(26)} \right]^T \quad , \quad (16)$$

402 respectively. The superscript  $(i)$  denotes individual measurements of a certain quantity.  
 403

**Figure 4.** Boundary conditions for the flow and transport simulations (a) and location of measurements for ESMDA updates (b). The labels M1-2 and T1-2 mark specific training and test locations, respectively.

404 After obtaining those measurements for every realisation, we update the param-  
 405 eter vectors containing the logarithm of all 4051 fracture aperture values using ESMDA.  
 406 For the scaled dimensionless measurements we assume a diagonal error covariance ma-  
 407 trix  $R$  with each element of the diagonal set to  $1 \times 10^{-5}$ . In this work, we do not ap-  
 408 ply any covariance localisation or inflation. We study the influence of ensemble size  $N_E$   
 409 and the number of ESMDA iterations  $N_{iter}$  on the results of the DA framework. For a  
 410 quantitative evaluation, we utilise the mean root-mean-square error defined as

$$411 \quad \text{M-RMSE}_\xi = \frac{1}{N_\xi} \sum_{i=1}^{N_\xi} \sqrt{\frac{1}{N_E} \sum_{j=1}^{N_E} \left( \xi_i^{(j)} - \xi_i^{(ref)} \right)^2} \quad , \quad (17)$$

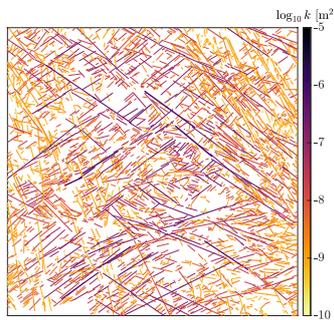

412 where  $\xi$  can represent either the log-apertures  $x$ , training measurements  $y$ , or test mea-  
 413 surement  $z$ . Here,  $\xi_i^{(j)}$  denotes the  $i$ -th entry in the corresponding vector of the  $j$ -th re-  
 414 alisation, and  $N_\xi$  refers to the length of that vector.

## 415 5 Results

416 In this section, we first analyse the prior ensemble obtained from FFSA by comparing it to the reference realisation from XFVM as well as to two prior ensembles from  
 417 the naïve stochastic approaches. Subsequently, we show that the prior ensemble from  
 418 FFSA outperforms the stochastic approaches in our DA framework.  
 419

### 420 5.1 Prior ensemble

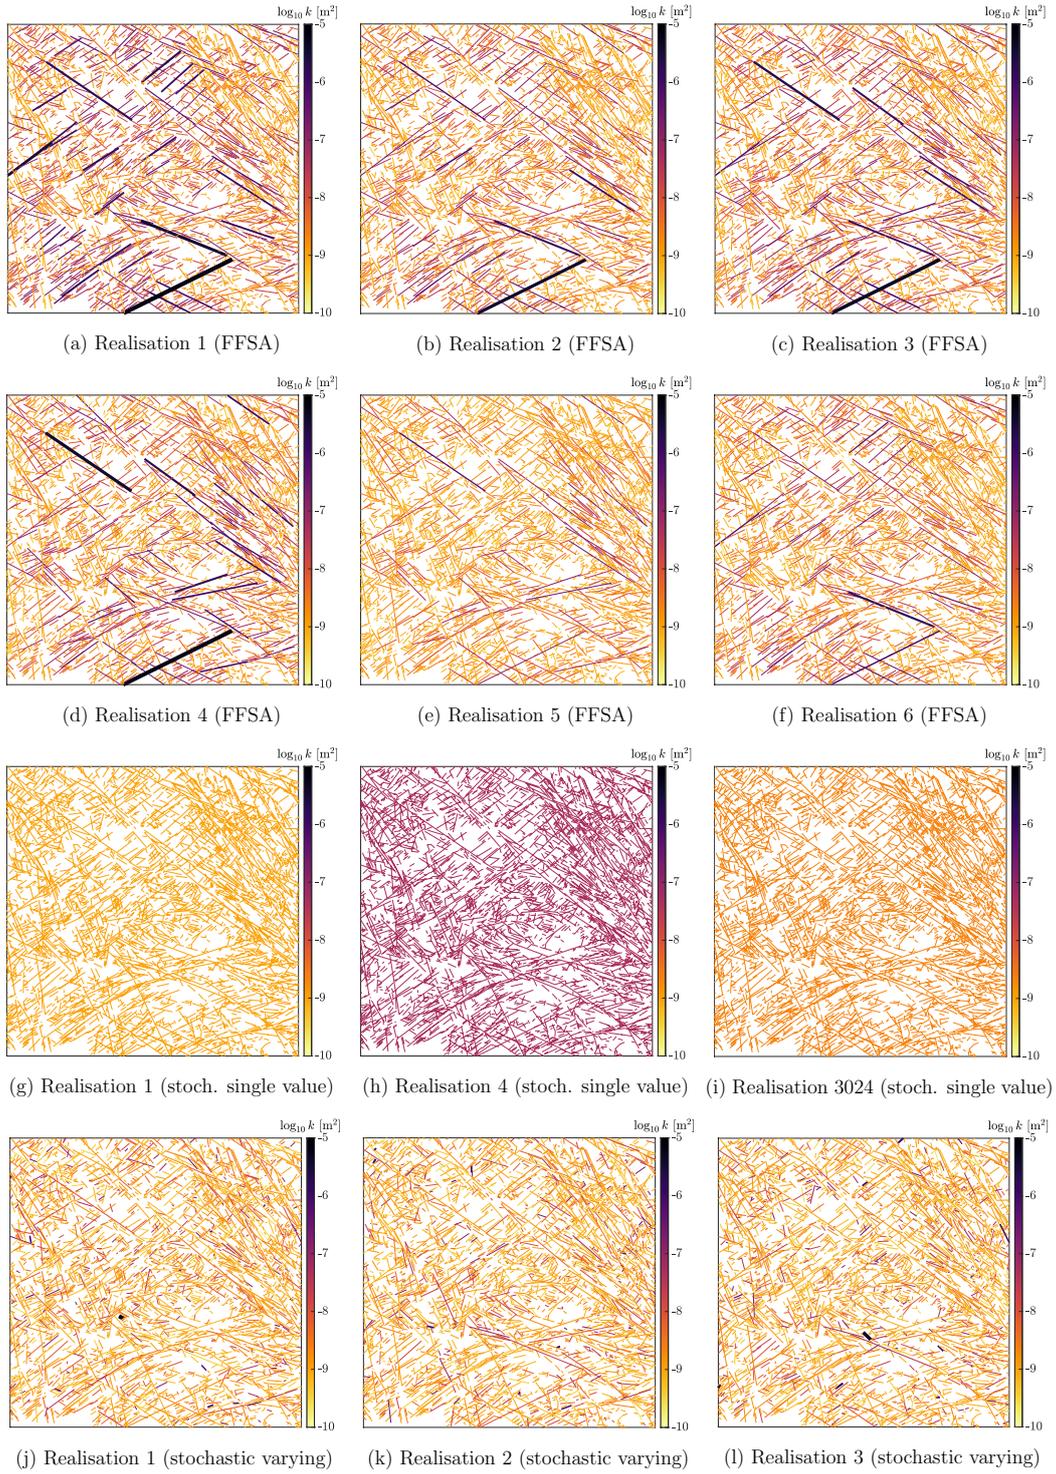

421 We first compare the maximum aperture value of each fracture. The reference re-  
 422 alisation obtained with XFVM is shown in Figure 5 and realisations 1 to 6 of the prior  
 423 ensemble generated with FFSA are depicted in Figures 6a–f, each obtained from a dif-  
 424 ferent set of sampled model parameter values. The realisations of the FFSA prior have  
 425 a notable variability which reflects the uncertainty in the model parameters as defined  
 426 in Table 1. Although none of the 6 prior realisations are particularly close to the refer-  
 427 ence, they nevertheless capture trends and features of it.

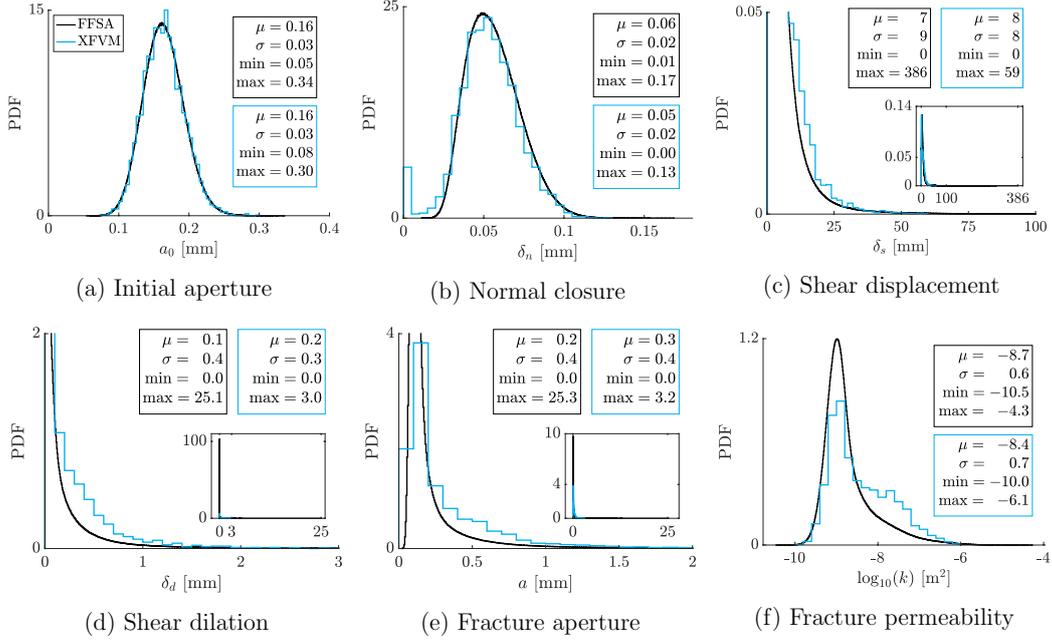

**Figure 5.** Reference realisation with XFVM. Line thickness corresponds to aperture width and line colour to  $\log_{10}$  of the fracture permeability.

428 From the prior ensemble with FFSA, we extract the unconditional PDF of the aper-  
 429 tures and related quantities from all fractures in all realisations (black curves in Figure 7).  
 430 The corresponding PDF from the reference simulation is shown in blue. Overall the two  
 431 curves in Figure 7 agree very well, although there are distinct differences. Firstly and  
 432 most notably, the FFSA prior underestimates the number of fractures with moderate frac-  
 433 ture permeability in the range of  $10^{-8} \text{ m}^2$  to  $10^{-7} \text{ m}^2$  (Figure 7f). We attribute this to  
 434 the slightly smaller mean shear displacement (Figure 7c) which we believe is a consequence  
 435 of neglecting fracture interactions. Secondly, the maximum values of shear displacement  
 436 and subsequently also aperture are significantly higher in the FFSA prior than in the  
 437 XFVM reference (Figure 7c). This occurs when very small friction and  $C_g$  values are sam-  
 438 pled for long and favourably oriented fractures in the FFSA prior. Such extreme values  
 439 are not present in the parameter set of the reference. Lastly, fracture interaction can mod-  
 440 ify the local stress field, resulting in situations where the effective normal stress can be-  
 441 come small or even negative. Therefore, some fractures in the XFVM reference experi-  
 442 ence little to no normal closure (Figure 7b). In contrast, all fractures in the FFSA prior  
 443 have positive effective normal stress and consequently some amount of normal closure,  
 444 as fracture interaction is neglected there. Even with these differences, we expect the en-  
 445 semble generated with FFSA to be a suitable prior for our DA framework.

446 We aim to compare the FFSA prior to two prior ensembles from naïve stochastic  
 447 approaches. For the first approach, named here stochastic single value prior, we sample  
 448 one value per realisation from the unconditional PDF of the FFSA prior (i.e. black curve  
 449 in Figure 7e) and set all apertures in that realisation to this value. For the second ap-

**Figure 6.** Realisations of the prior ensemble with FFSA (a–f), stochastic single value (g–i) and stochastic varying (j–l). Line thickness corresponds to aperture width and line colour to  $\log_{10}$  of the fracture permeability.

**Figure 7.** Combined histogram of the values of all 4051 fractures in 5000 realisations with FFSA (black) and the reference simulation with XFVM (blue)

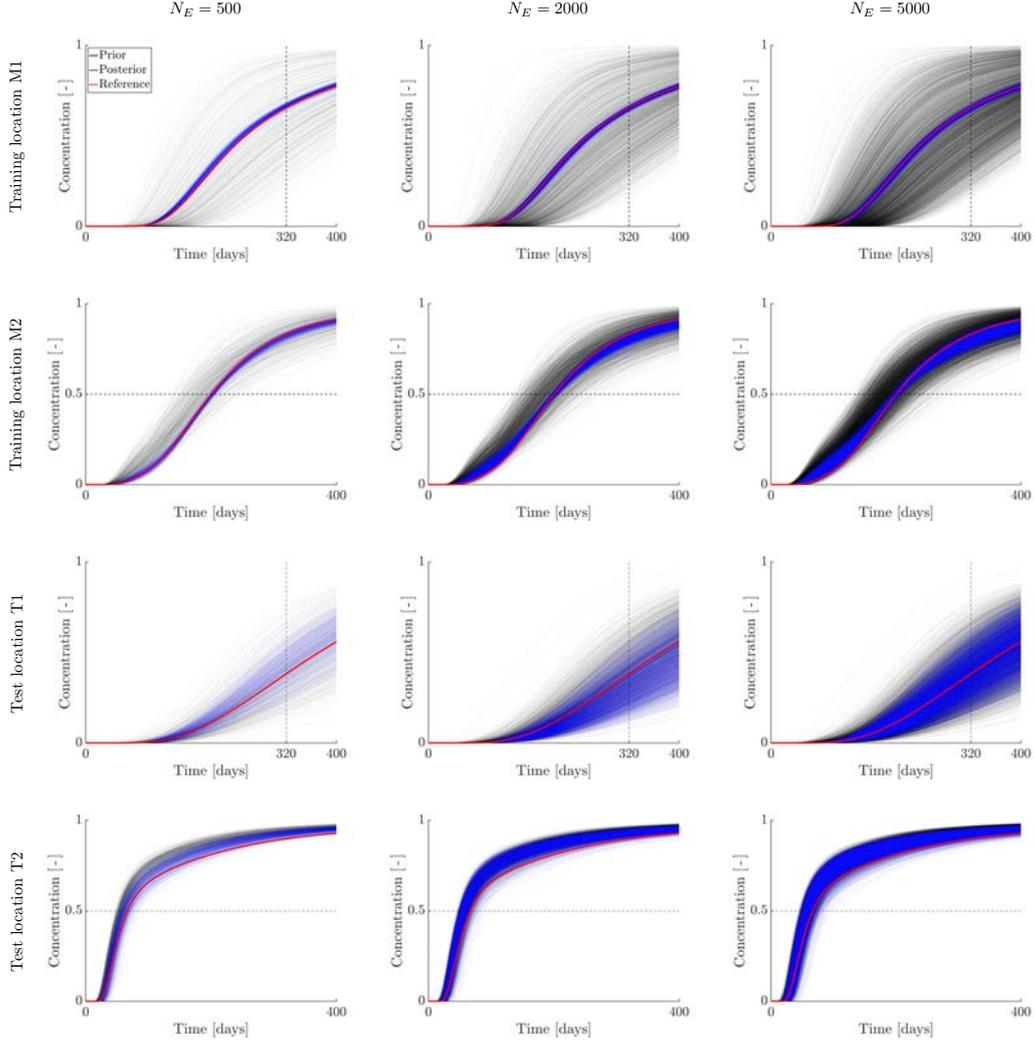

450 proach, named stochastic varying prior, we independently sample aperture values for ev-  
 451 every fracture in every realisation from the same PDF. Figures 6g–l show realisations of  
 452 those two prior ensembles. Visually, the FFSA prior is much closer to the reference than  
 453 the stochastic ones, even though all three prior ensembles follow the same unconditional  
 454 PDF.

## 455 5.2 Posterior ensemble

456 Now we want to investigate how the three different prior ensembles perform in our  
 457 DA framework. We first analyse the measurements and then the apertures of the pos-  
 458 terior ensembles.

459 We monitor the evolution of the tracer concentration over time at specific locations  
 460 on the boundary of the domain (Figure 4b). Figure 8 shows the resulting breakthrough  
 461 curves at two training and two test locations for three prior ensembles of different sizes  
 462 generated with FFSA and corresponding posterior ensembles. At the training locations,  
 463 either a concentration or arrival time measurement is taken for the ESM DA update, whereas  
 464 at test locations, the breakthrough curve measurement is solely used for evaluating the  
 465 performance of ESM DA but not in the update itself. The breakthrough curves of the  
 466 prior ensembles have a considerable spread at all four locations as a result of the uncer-  
 467 tain fracture apertures. At training locations, the posterior ensembles closely match the  
 468 reference realisation from XFVM. We obtain a good match of the entire breakthrough  
 469 curves even though only a single concentration or arrival time measurement per loca-  
 470 tion is used. In test locations, the level of uncertainty is only slightly reduced, and a con-  
 471 siderable spread remains in the posterior ensembles. With the FFSA prior we get essen-  
 472 tially converged results already for an ensemble size of 500, as the results remain con-  
 473 sistent for larger ensemble sizes.

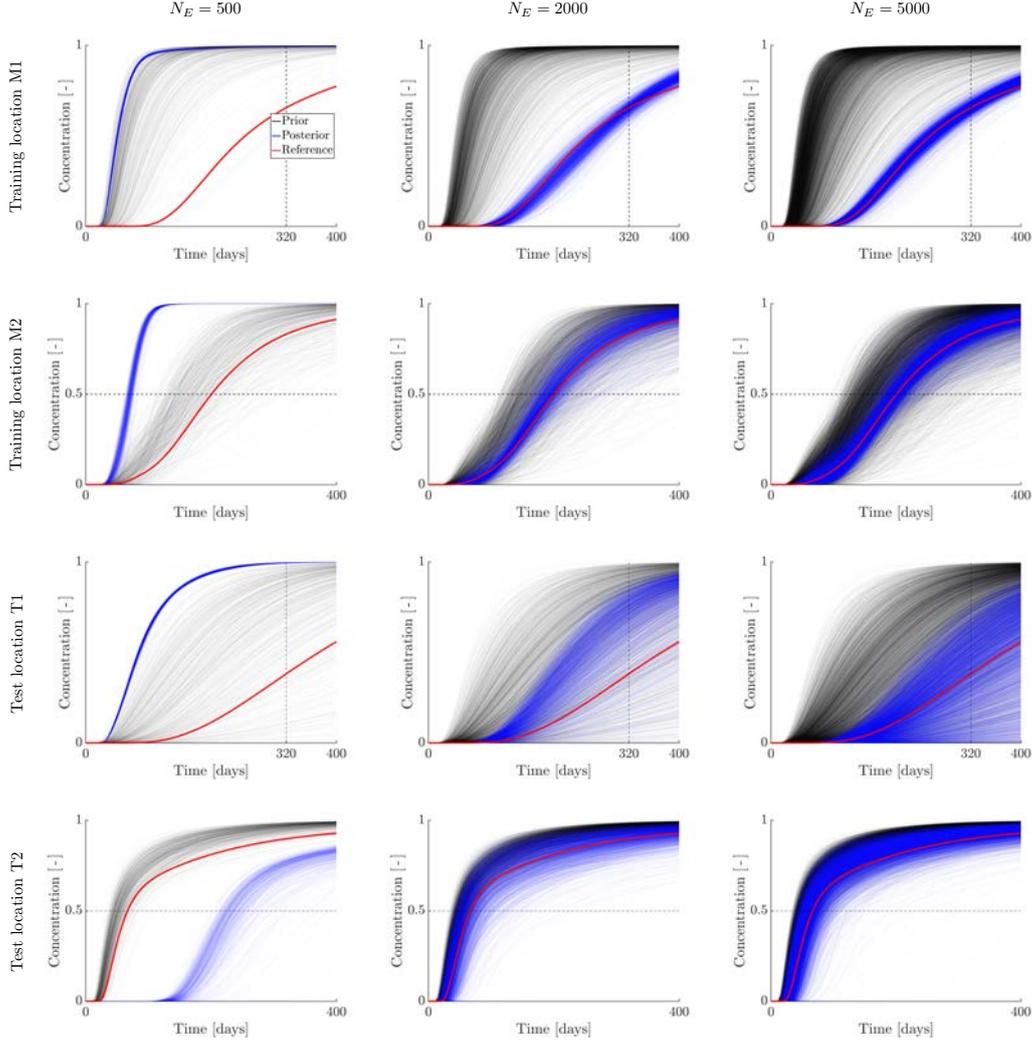

474 The same breakthrough curves for the stochastic varying prior are shown in Fig-  
 475 ure 9. Here, the posterior of the smallest ensemble size (i.e., with  $N_E = 500$ ) collapsed

**Figure 8.** Breakthrough curves of the FFSA prior. The prior ensemble is in black, the posterior ensemble in blue and the XFVM reference in red. The locations of two training and two test locations are indicated in Figure 4. The columns correspond to different ensemble sizes and the dashed lines indicate the measurements.

476 and converged to a wrong solution. Results with larger ensemble sizes are generally fine;  
 477 however, test location T1 indicates that  $N_E = 2000$  is not large enough for full con-  
 478 vergence regarding ensemble size. Compared to the FFSA prior, the ensemble spread is  
 479 larger for the stochastic varying prior, both in the prior ensembles and consequently also  
 480 in the posterior ensembles.

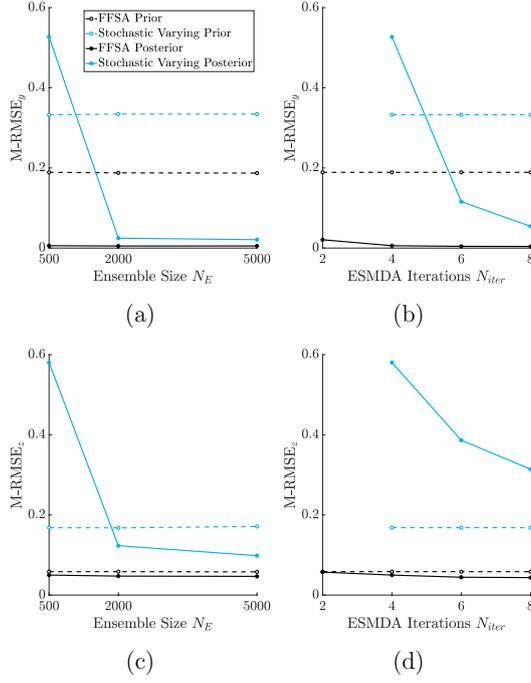

481 We quantify the performance of the FFSA and stochastic varying priors with the  
 482 mean root-mean-square error of the training and test measurements, as defined in Equa-  
 483 tion (17), for different ensemble sizes and numbers of ESMDA iterations (Figure 10a–  
 484 d). Comparing the FFSA posterior to its prior, we see that the error in the training mea-  
 485 surements is drastically reduced, while the error in the test measurements is only slightly  
 486 smaller. An ensemble size of 500 and 4 ESMDA iterations is sufficient to achieve satis-  
 487 factory results for the FFSA prior. For the stochastic varying prior however, a combi-  
 488 nation of ensemble size and number of ESMDA iterations beyond our computational ca-

**Figure 9.** Breakthrough curves of the stochastic varying prior. The prior ensemble is in black, the posterior ensemble in blue and the XFVM reference in red. The locations of two training and two test locations are indicated in Figure 4. The columns correspond to different ensemble sizes and the dashed lines indicate the measurements.

489 probabilities is required for converged results. Compared to FFSA, the training and test er-  
 490 rors of the stochastic varying prior are 1.8 and 3.0 times larger, respectively. For the com-  
 491 bination with the smallest errors (i.e., with  $N_E = 5000$  and  $N_{iter} = 4$ ), the correspond-  
 492 ing ratios in the posterior are 3.9 and 2.1. In short, the results from the FFSA prior match  
 493 the measurements better than the ones from the stochastic varying prior, but the lat-  
 494 ter also produces a posterior with substantially reduced measurement errors, given a suf-  
 495 ficiently large ensemble size.

496 A significant difference exists between the updated fracture apertures obtained with  
 497 the two methods. Figure 11 shows some realisations of the posterior ensembles obtained  
 498 from the FFSA and stochastic varying priors for  $N_E = 5000$  and  $N_{iter} = 4$ . Gener-  
 499 ally, the posterior realisations of FFSA (Figure 11a-f) are more similar to the reference  
 500 than the corresponding realisations from the prior ensemble (Figure 6a-f), and the vari-  
 501 ability of the realisations in the ensemble is reduced. For example, realisations 5 and 6

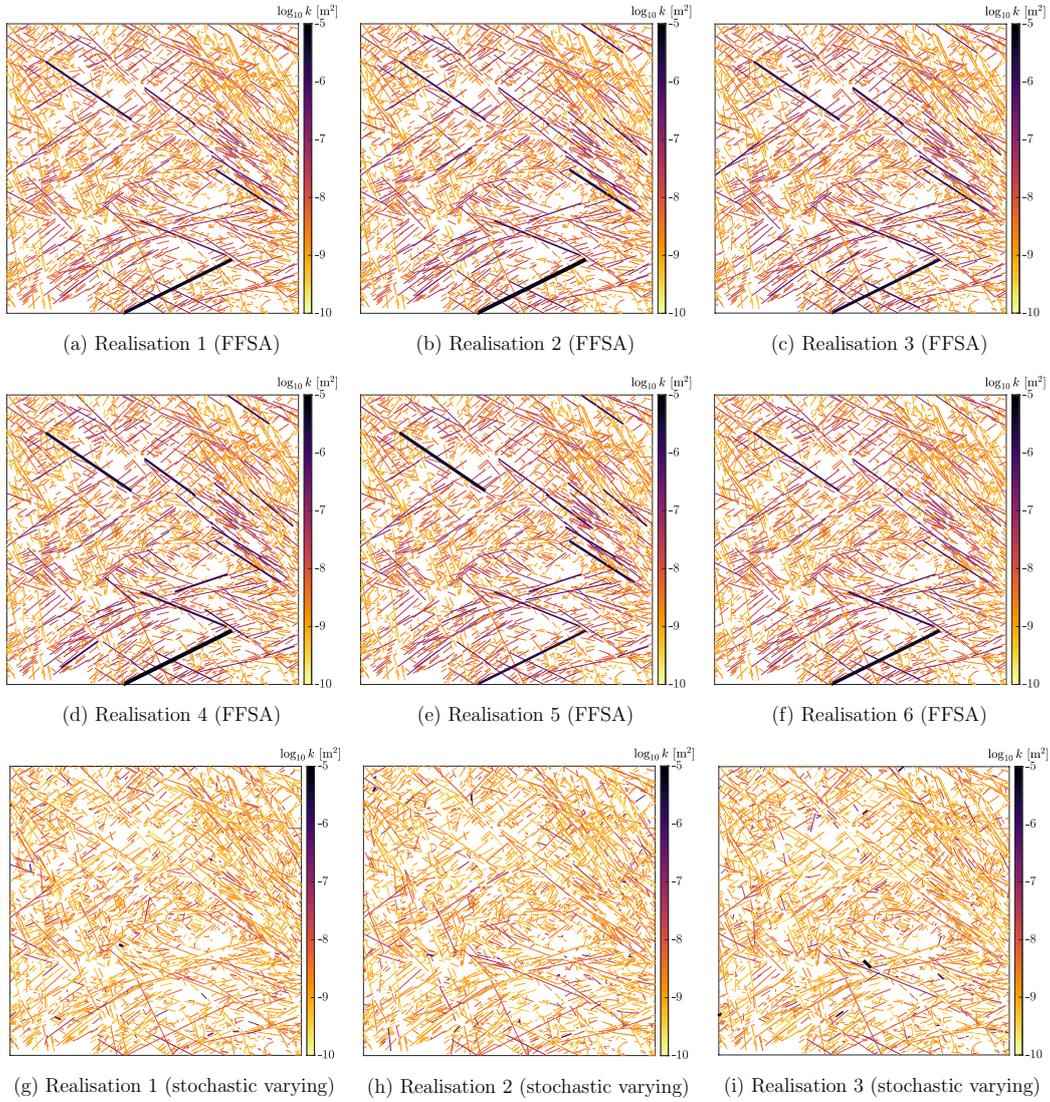

**Figure 10.** Mean root-mean-square error (M-RMSE) of training (a, b) and test (c, d) measurements calculated with Equation (17). Figures (a, c) show results for  $N_{iter} = 4$  and (b, d) for  $N_E = 500$ .

502 show overall increased apertures, and the apertures of the prominent long fractures are  
 503 slightly reduced in realisation 1. However, the posterior realisations are not an exact match  
 504 to the reference, as the apertures of long and optimally oriented fractures are still over-  
 505 estimated, while the ones of many short fractures are underestimated. These qualita-  
 506 tive observations are supported by Figure 12a, which shows a slight improvement in the  
 507 unconditional PDF of the FFSA posterior compared to the prior. Conversely, the pos-  
 508 terior realisations of the stochastic varying priors (Figure 11g-i) appear to be almost iden-  
 509 tical to the corresponding prior realisations (Figure 6j-l), and only fractures near mea-  
 510 surement locations are visibly improved. The corresponding unconditional PDF shows  
 511 extreme minimum and maximum permeability values which reach unphysical levels. The  
 512 mean root-mean-square errors of the log-apertures (Figure 12b-c) show a marginal im-  
 513 provement for FFSA but no improvement for the stochastic varying prior. The drastic  
 514 increase in the posterior errors for the stochastic varying prior arises from an ensemble  
 515 collapse to a wrong solution.

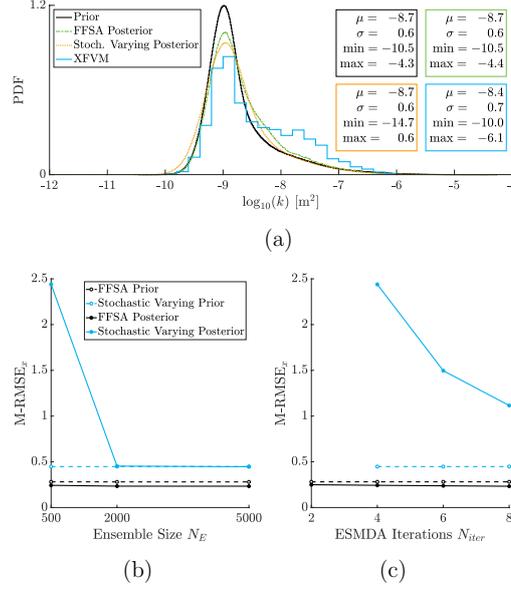

516 The stochastic single value prior fails to produce satisfactory results in the DA frame-  
 517 work, leading to ensemble collapse regardless of the ensemble size and number of ESMDA  
 518 iterations. In light of this, we calculate the root-mean-square error of the training mea-  
 519 surements for each prior realisation as

$$520 \quad \text{RMSE}_y^{(j)} = \sqrt{\frac{1}{N_y} \sum_{i=1}^{N_y} \left( y_i^{(j)} - y_i^{(ref)} \right)^2} \quad (18)$$

521 and find the one with the smallest error (Figure 13a). The best realisation has an aper-  
 522 ture of 0.16 mm and is shown in Figure 6i. Although some breakthrough curves obtained  
 523 from this realisation show somewhat acceptable agreement with the reference (Figure 13c),  
 524 others display substantial errors (Figure 13b). As expected, it is therefore not possible

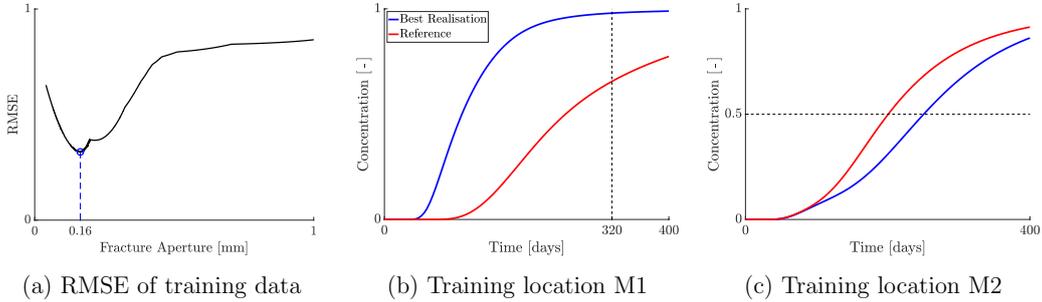

**Figure 11.** Realisations of the posterior ensemble obtained from the FFSA prior (a–f) and the stochastic varying prior (g–i) for  $N_E = 5000$  and  $N_{iter} = 4$ . Line thickness corresponds to aperture width and line colour to  $\log_{10}$  of the fracture permeability.

**Figure 12.** Combined histogram of fracture permeability values of all 4051 fractures for  $N_E = 5000$  and  $N_{iter} = 4$  (a) and mean root-mean-square error (M-RMSE) of log-apertures calculated with Equation (17) for  $N_{iter} = 4$  (b) and  $N_E = 500$  (c)

525 to match the complex flow and transport behaviour of the reference when using only a  
 526 single value for all fracture apertures.

**Figure 13.** Root-mean-square error (RMSE) of the training data for the stochastic single value prior shows that the realisation with a fracture aperture of 0.16 mm has the smallest error (a). Breakthrough curves at two locations as indicated in Figure 4 for this best realisation in blue and the XFVM reference in red (b, c).

## 6 Discussion

527  
 528 The FFSA provides reasonable approximations of the fracture apertures in a scenario  
 529 dominated by shear dilation. It is thereby substantially faster than a geomechanical  
 530 simulator like XFVM. For the presented fracture model, the FFSA takes less than  
 531 a minute while the XFVM runs for several days. However, neither code is fully optimised  
 532 for speed, and there is potential to significantly improve the computational efficiency of  
 533 XFVM. The speed of FFSA makes it an attractive option for generating prior ensem-

534 bles for DA purposes, as typically a large number of realisations is required. In contrast,  
 535 using geomechanical simulators for this task might become computationally prohibitive.

536 The FFSA is only exact for a single isolated fracture with constant friction angle  
 537 and it neglects fracture interactions. This leads to modelling errors (see Appendix A3  
 538 for a direct comparison to XFVM), particularly as shearing of a fracture can change the  
 539 local stress field considerably. To compensate for those errors, we introduce additional  
 540 uncertainty through the parameter  $C_g$ , a proportionality factor between shear stress and  
 541 shear displacement. While this approach gives overall satisfactory results, moderate frac-  
 542 ture permeabilities are under-represented in the PDF of the FFSA prior ensemble com-  
 543 pared to the one of the reference realisation obtained with XFVM (Figure 7f), indicat-  
 544 ing that the chosen approach is not yet optimal.

545 With the current approach, the fracture length has a much larger influence on the  
 546 shear displacement than the parameter  $C_g$  because the uncertainty in  $C_g$  is much smaller  
 547 than the variation of the fracture length in our model (Equation (5)). Increasing the un-  
 548 certainty in  $C_g$  would however lead to more extreme values for long fractures. There-  
 549 fore, an improved approach should increase the probability of moderate apertures for short  
 550 fractures without generating extremely high apertures for long fractures. For example,  
 551 we could model the uncertainty of  $C_g$  as a function of fracture length or introduce an  
 552 additive uncertainty directly to the fracture aperture in Equation (7). Another approach  
 553 is adding additional uncertainty to the stress state, thereby modelling the change in the  
 554 local stress state at one fracture due to the shearing of other fractures. Further, we could  
 555 improve the FFSA itself by incorporating knowledge of the surrounding fracture geom-  
 556 etry or using a hierarchical approach, i.e., first estimating shear displacement and aper-  
 557 tures of the large fractures, and then deriving the local stress field at the smaller ones.

558 Even without the above-mentioned improvements, the FFSA produces prior real-  
 559 isations that are much closer to the reference than the two naïve stochastic approaches.  
 560 Subsequently, the FFSA prior also leads to a better posterior ensemble than the stochas-  
 561 tic approaches. We can state that, at least in our setting, a better prior leads to a bet-  
 562 ter posterior and it is therefore crucial to model the prior appropriately.

563 In this work, we confirm that it is not possible to retrieve the complex flow and trans-  
 564 port behaviour of the reference when using only a single value for all fracture apertures.  
 565 Even when the optimal single aperture is used, the resulting realisation still has a con-  
 566 siderable error in the measurements, leading to completely wrong estimates of some break-  
 567 through curves (Figure 13). The stochastic single value prior led to an ensemble collapse  
 568 in our DA framework irrespective of the ensemble size. We believe this collapse results  
 569 from a combination of factors. Firstly, the relations between the single aperture value  
 570 and certain measurements become constant above or below specific thresholds, result-  
 571 ing in a loss of ensemble variation for those measurements and, in extreme cases, an iden-  
 572 tical measurement value for all realisations. Secondly, some of those relations exhibit non-  
 573 monotonic behaviour such that realisations can be attracted by non-optimal local min-  
 574 ima. Thirdly, the stochastic single value prior generates realisations confined to a lim-  
 575 ited subset with highly correlated measurements, leading to numerical issues when cal-  
 576 culating the Kalman gain (Equation (A8) in Appendix A2). Lastly, one reference mea-  
 577 surement lies entirely outside the range of the prior ensemble. Consequently, we were  
 578 unable to obtain any DA results for this prior.

579 While the stochastic single value prior is too restrictive, the stochastic varying prior  
 580 bears too much uncertainty. It does not incorporate all available knowledge, such as cor-  
 581 relations of fracture aperture with length and orientation. As a consequence, a large en-  
 582 semble size is required to avoid undersampling. In this study, undersized ensembles col-  
 583 lapsed and converged to wrong solutions. Results suggest that a smaller ensemble size  
 584 might be possible with more ESMDA iterations, but the required combination of ensem-  
 585 ble size and number of ESMDA iterations is beyond our current computational capabil-

ities, and thus, our results with this prior are not fully converged. Nevertheless, we expect that results with a much larger ensemble size are similar to the ones from our best combination ( $N_E = 5000$ ,  $N_{iter} = 4$ ). With this combination, we obtain a posterior ensemble that matches the training measurements, i.e., measurements that are used for the ESMDA update, quite well. The improvement in the test measurements, which are solely used for evaluating the outcome of the DA framework, is smaller and a considerable amount of uncertainty remains. The apertures of the posterior realisations differ however significantly from the reference realisation, with updates predominantly occurring near measurement locations. This emphasises the importance of considering more than just the (training) measurements when evaluating the effectiveness of a DA framework.

With the FFSA prior, we obtain posterior realisations with an improved estimation of the apertures compared to the ones from the prior ensemble, even though a considerable difference to the reference realisation remains. The posterior ensemble matches the training measurements of the reference realisation very well, while the test measurements are only marginally improved, indicating that the improvements in flow and transport are mostly limited to the vicinity of training measurements. More measurements, especially also from the interior of the domain, are needed to further improve the estimation of aperture as well as the flow and transport. However, the number of measurement locations already exceeds what one can expect in field studies and a complete observation of flow and transport is only possible in lab experiments such as e.g. in Flemisch et al. (2023). While there is room for improvement, the posterior from the FFSA prior gives good estimates of the fracture apertures, which can be used for performance estimation and risk assessment in subsurface applications. Concrete examples involve optimal placement of boreholes for injection or extraction, expected heat extraction in a geothermal reservoir, or preventing potential contamination of nearby aquifers.

Our results, especially the ones with the stochastic varying prior, suggest that most apertures only have a negligible influence on the measurements at the boundaries. While this is expected to some degree, we also identify three constraints in our study setup that artificially limit the influence of the fractures. Firstly, we use a first-order transport scheme which leads to a considerable amount of numerical diffusion. Diffusion smears out the concentration front and thus dampens the effects of the fractures. We could avoid this by using a higher-order scheme and only include a controlled amount of physical diffusion. Secondly, the sensitivity of the fracture apertures on the flow and transport measurements is highly dependent on the ratio of matrix to fracture permeability (Phillips, 1991; Matthäi & Belayneh, 2004). In cases with very low matrix permeability, the flow is governed by the fracture topology, favouring flow paths with minimal matrix distances. In this regime, fracture aperture influences flow only when equivalent flow paths exist. Conversely, in cases with very high matrix permeability, flow predominantly occurs within the matrix, largely independent of fracture parameters. Only in the intermediate range of matrix permeabilities do the fracture apertures have a significant influence on flow and transport. We have not optimised the matrix permeability for maximum sensitivity of the apertures, as it is not a tuning parameter in practical scenarios. Lastly, boundary conditions might contribute to these limitations as well. By imposing a fixed pressure on the domain's boundary, we disregard that the fractured rock typically extends beyond the region of interest. Flow and transport near the boundary are strongly influenced by the boundary condition. Alternative approaches, such as implementing infinite boundary conditions or using measurements only in the interior of the domain, might decrease the influence of the boundary conditions on the measurements and represent real-world conditions more accurately.

Nevertheless, the posterior from the FFSA prior also shows slightly improved apertures in the interior of the domain. In such priors, apertures of fractures with similar length and orientation are correlated. Hence, fractures in the interior of the domain are corre-

639 lated to measurements through similar fractures near the measurement locations and there-  
 640 fore also updated by ESMDA. In reality, apertures are correlated with length and ori-  
 641 entation (C. A. Barton et al., 1995; Baghbanan & Jing, 2008; N. Barton & Quadros, 2015;  
 642 X. Zhang et al., 2021), and such indirect updates are desired to some extent. However,  
 643 the current implementation of the FFSA prior overestimates these correlations, leading  
 644 to a posterior with deficient variability. We expect that these issues can be resolved by  
 645 the above-mentioned improvements of FFSA.

646 In this study, we used a geological scenario where the generation of the fracture aper-  
 647 tures occurs before the reservoir characterisation with the tracer test. However, inject-  
 648 ing fluid into the reservoir during the tracer test alters the effective normal stresses at  
 649 the fractures and consequently fracture aperture, which in turn affects the flow field. In  
 650 future works, it is therefore desirable to couple flow and mechanics and consider poroe-  
 651 lasticity. A further step towards a more realistic setting is the extension to 3D, which  
 652 is straightforward for FFSA. The far-field stresses can be projected onto the fracture planes  
 653 with a 3D version of Equations (1) and (2), and the process of approximating the max-  
 654 imum shear displacement is similar to that in 2D. For that purpose, Chinnery (1969) lists  
 655 values of the proportionality factor  $C_g$  for various fracture shapes. Special attention must  
 656 be given to the definition of fracture length, however. In future works, we could also con-  
 657 sider additional model parameters as uncertain, such as matrix permeability and poros-  
 658 ity, and allow for uncertainties in the boundary conditions of the tracer test. Here, we  
 659 consider rock properties as spatially homogeneous, but we could also model them with  
 660 e.g. Gaussian random fields as in Liem et al. (2022).

661 Arguably the biggest assumption in this work is that we know the fracture geom-  
 662 etry (i.e., location, orientation and length of each fracture) *a priori* and exactly. In re-  
 663 ality, the fracture geometry is usually associated with substantial uncertainty, as only  
 664 sparse borehole data and statistical information are available. Nevertheless, valuable in-  
 665 sight is obtained from this study, as discussed above. We see this study as a necessary  
 666 intermediate step towards a more realistic setup that eventually also includes uncertain  
 667 fracture geometry. Several existing tools can be used or built upon to generate physi-  
 668 cally meaningful realisations of a fracture geometry, e.g. as in Hyman et al. (2015), Lei  
 669 et al. (2017), Gläser et al. (2020), and Paluszny et al. (2020). It should then be straight-  
 670 forward to update input parameters of the fracture generator (such as statistics of e.g.  
 671 fracture length or density). It is however very challenging to update the actual fracture  
 672 geometry itself. Parametrising the generated fracture geometry efficiently and effectively  
 673 for this purpose is complex as the number of fractures can vary between realisations, and  
 674 a fracture from one realisation generally does not have a bijectively related fracture in  
 675 other realisations. Existing approaches based on level set function or Hough transform  
 676 (Ping et al., 2017; Chai et al., 2018; Yao et al., 2018), to our knowledge, have not been  
 677 applied to complex large fracture geometries yet. The task becomes even more challeng-  
 678 ing if the parameterisation should also reflect relations between fractures, including frac-  
 679 tures terminating against other fractures and formation history. Additionally, automatic  
 680 remeshing of the updated fracture geometry might be challenging as arbitrary small dis-  
 681 tances or angles may occur. For this purpose, non-conforming discretisation as in the  
 682 embedded discrete fracture model (EDFM) is beneficial.

## 683 7 Conclusion

684 In this work, we suggest using the far-field stress approximation (FFSA), a proxy  
 685 model designed to estimate fracture apertures in shear-dominated scenarios, to gener-  
 686 ate prior ensembles for data assimilation (DA). The FFSA captures the general trends  
 687 effectively, albeit with some inherent errors due to neglecting fracture interactions. We  
 688 use FFSA to generate realistic and computationally efficient prior ensembles for ensemble-  
 689 based data assimilation. To compensate for modelling errors, we introduce supplement-  
 690 ary uncertainty in one model parameter. Comparing FFSA priors to those from two naïve

691 stochastic approaches reveals notable differences. While all methods share the same un-  
 692 derlying unconditional PDF, FFSA-derived realisations are much closer to the reference  
 693 realisation from a geomechanical simulator.

694 Employing ESMDA, we update fracture apertures with flow and transport data.  
 695 The posterior ensemble obtained from the FFSA prior matches the flow and transport  
 696 behaviour as well as the apertures, although some differences remain. In contrast, the  
 697 posterior ensemble obtained from an unconditional sampling of the apertures (i.e., a stochas-  
 698 tic varying prior) yields apertures that substantially deviate from the reference despite  
 699 matching training measurements. In addition, a significantly larger ensemble size is re-  
 700 quired than for the FFSA prior, increasing overall computational cost. The third prior,  
 701 which uses the same value for all fracture apertures in a realisation, cannot match the  
 702 complex flow and transport behaviour of our synthetic reference. Our results show a cor-  
 703 relation between the prior and posterior uncertainties and highlight the importance of  
 704 a good estimation of the prior ensemble. We expect that those results also apply to other  
 705 ensemble-based DA methods, for example particle filters.

706 While the current form of FFSA already produces reasonable results, opportuni-  
 707 ties for improvement, particularly in addressing modelling errors through additional un-  
 708 certainties, remain. To achieve this, we plan to conduct a more detailed study with the  
 709 FFSA in a separate work. Further potential improvements for the ESMDA framework  
 710 include constructing a prior ensemble that combines realisations from different methods  
 711 and the use of adaptive localisation. Moreover, we aim to make the framework more re-  
 712 alistic by coupling flow and transport with mechanics, incorporating additional physics  
 713 like heat transport, and eventually accounting for uncertainty in fracture geometry.

## 714 **Appendix A Appendix**

### 715 **A1 Fracture Aperture Model of Barton and Bandis**

716 In this work, we use the constitutive model of Barton and Bandis (N. Barton &  
 717 Choubey, 1977; N. Barton, 1982; Bandis et al., 1983; N. Barton et al., 1985) where the  
 718 aperture of a fracture  $a$  is a combination of the initial aperture  $a_0$ , closure due to nor-  
 719 mal stress  $\delta_n$  and dilation due to shearing  $\delta_d$  (Equation (7)).

720 The initial aperture

$$721 \quad a_0 = \frac{JRC}{5} \left( 0.2 \frac{\sigma_c}{JCS} - 0.1 \right) \quad (A1)$$

722 corresponds to the fracture aperture under stress-free conditions. It is a function of the  
 723 (peak) joint roughness coefficient  $JRC$  and the amount of joint alteration described by  
 724 the ratio of unconfined compressive strength of the rock  $\sigma_c$  and joint wall compression  
 725 strength  $JCS$ . In this work, we assume that the fractures are unaltered and unweath-  
 726 ered (i.e.  $JCS = \sigma_c$ ), and therefore the initial aperture depends on the surface rough-  
 727 ness only.

728 Assuming a positive effective normal stress  $\sigma_{eff} > 0$ , the amount of closure is

$$729 \quad \delta_n = \frac{\sigma_{eff} v_m}{K_{ni} v_m + \sigma_{eff}}, \quad (A2)$$

730 where  $v_m$  and  $K_{ni}$  are the maximum possible closure and the initial normal stiffness, re-  
 731 spectively. Under increasing normal stress, more and more asperities are in contact and  
 732 consequently, the normal stiffness of the fracture increases. The model of Barton and Ban-  
 733 dis is not applicable if fluid pressure exceeds normal stress (i.e. for negative  $\sigma_{eff}$ ) and  
 734 tensile opening occurs.

735 A key feature of the model of Barton and Bandis is that the friction angle

$$736 \quad \phi' = JRC_{mob} \log_{10} \left( \frac{JCS}{\sigma_{eff}} \right) + \phi_r \quad (A3)$$

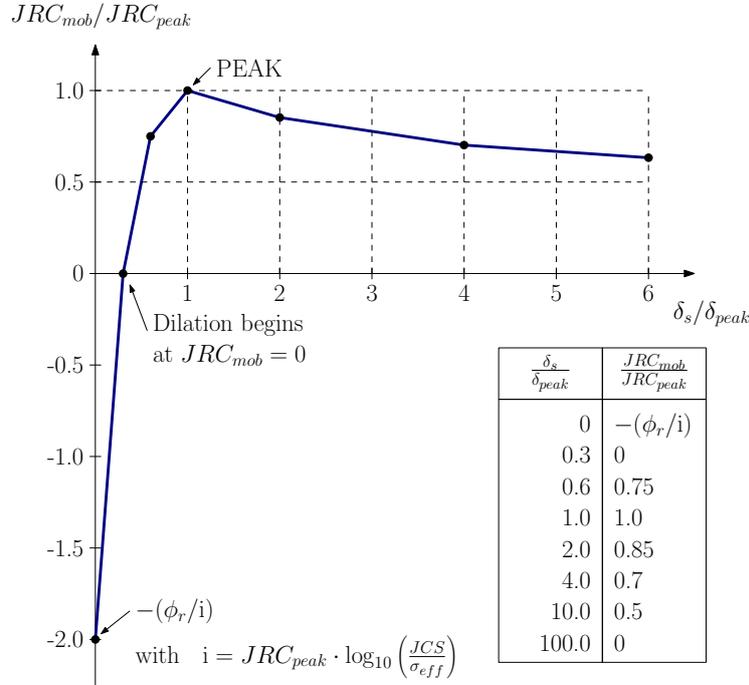

737 and dilation angle

$$738 \quad \phi_d = \frac{1}{M}(\phi' - \phi_r) = \frac{1}{M} JRC_{mob} \log_{10} \left( \frac{JCS}{\sigma_{eff}} \right) \quad (A4)$$

739 are not constant but vary with the amount of shear displacement. This dependency is  
 740 modelled with the mobilised joint roughness coefficient  $JRC_{mob}$  (Figure A1). The peak  
 741 shear displacement  $\delta_{peak}$  corresponds to the amount of shearing when peak shear strength  
 742 is reached. Here, we use

$$743 \quad \delta_{peak} = 0.0077L^{0.45} \left( \frac{\sigma_{eff}}{JCS} \right)^{0.34} \cos \left( JRC \cdot \log_{10} \left( \frac{JCS}{\sigma_{eff}} \right) \right), \quad (A5)$$

744 as proposed by Asadollahi and Tonon (2010). For pre-peak shearing ( $\delta_s < \delta_{peak}$ ), the  
 745 degradation of the few asperities that are in contact increases the interlocking between  
 746 the two fracture surfaces and consequently increases the friction. For post-peak shear-  
 747 ing ( $\delta_s > \delta_{peak}$ ) on the other hand, roughness is getting destroyed and smoothed out.  
 748 Subsequently, shear strength and dilation angle are steadily reduced. For an infinite amount  
 749 of shearing, the friction angle is equal to the residual friction angle and the dilation angle  
 750 approaches zero.

**Figure A1.** Mobilised joint roughness coefficient  $JRC_{mob}$  as a function of shear displacement  $\delta_s$ . Figure reproduced from Liem et al. (2022), original figure from N. Barton (1982) and N. Barton et al. (1985).

751 For the damage coefficient  $M$  in Equation (A3) we use the formula proposed by  
 752 N. Barton and Choubey (1977)

$$753 \quad M = 0.7 + JRC \left/ \left[ 12 \log_{10} \left( \frac{JCS}{\sigma_{eff}} \right) \right] \right. . \quad (A6)$$

754 In this work, we neglect the decrease in aperture for small shear displacements and there-  
 755 fore integrate only over positive dilation angles in Equation (6). The model of Barton

and Bandis has been developed for fractures with a constant fluid pressure and thus a relatively constant effective normal stress. In our simulation however, the fluid pressure is steadily increased and the effective normal stress might become very small in some fractures or even locally negative for some segments in the reference simulation with XFVM. We therefore approximate  $\sigma_{eff}$  in Equations (A3) to (A6) as

$$\sigma_{eff} \approx \sigma_n - \frac{1}{2} \left( \frac{|\sigma_s|}{\tan \phi_r} + p_f^{end} \right), \quad (\text{A7})$$

where we calculate  $\sigma_n$  and  $\sigma_s$  with Cauchy's equations (Equations (1) to (2)) and  $p_f^{end}$  is the target fluid pressure.

## A2 Details of ESMDA

In Equation (12), we use a stochastic version of the Kalman update in the ESMDA. Following Asch et al. (2016), we approximate the Kalman gain

$$K = P^f H^T [HP^f H^T + R]^{-1} \simeq X^f (Y^f)^T [Y^f (Y^f)^T]^{-1} \quad (\text{A8})$$

with the normalised anomalies

$$[X^f]_i = \frac{1}{\sqrt{N_E - 1}} \left( x_i^f - \frac{1}{N_E} \sum_{j=1}^N x_j^f \right) \quad \text{and} \quad (\text{A9})$$

$$[Y^f]_i = \frac{1}{\sqrt{N_E - 1}} \left( (y_i^f + u_i) - \frac{1}{N_E} \sum_{j=1}^N (y_j^f + u_j) \right). \quad (\text{A10})$$

Here,  $P^f$  is the forecast error covariance matrix and  $H$  the linearised version of the observation operator  $\mathcal{H}(\cdot)$ , which maps the input vector  $x_i$  to the measurement vector  $y_i$ .

In order to guarantee a correct posterior distribution in a linear model with Gaussian error statistics, the ESMDA inflates the measurement error covariance matrix  $R$  in Equation (12), i.e.,

$$\tilde{R}_m = \alpha_m R \quad \text{such that} \quad \sum_{m=1}^M \frac{1}{\alpha_m} = 1, \quad (\text{A11})$$

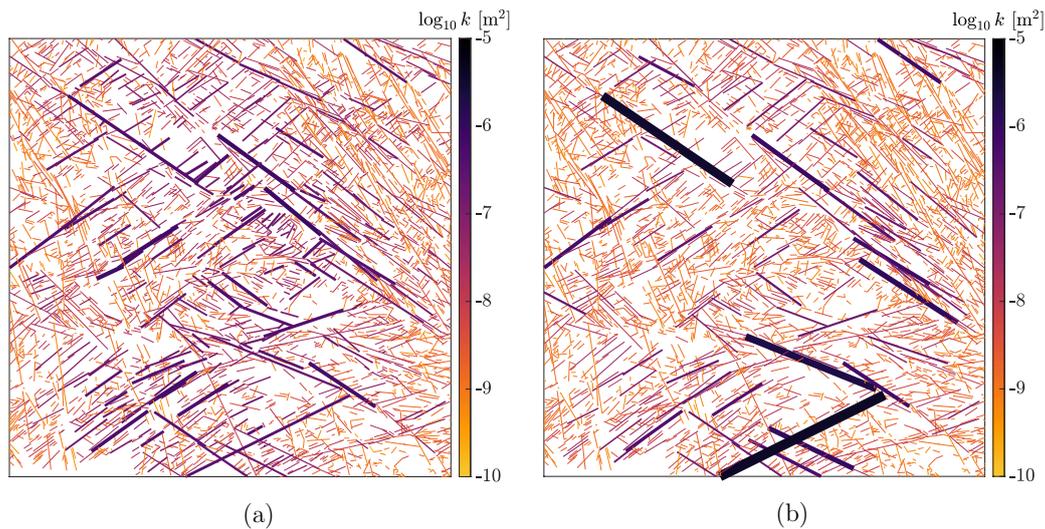

where  $M$  is the number of ESMDA iterations (A. A. Emerick & Reynolds, 2013). In this study, we use a constant inflation factor  $\alpha_m = M \forall m$ .

## A3 Comparison of XFVM and FFSA

Figure A2 shows the results of XFVM and FFSA for the exact same underlying model parameters (i.e. the values from the last column of Table 1) and  $C_g = 1$ . The FFSA captures the general trends and some apertures agree quite well. However, there are also quite large differences for many fractures. Most notably, the apertures of long, optimally oriented fractures are overestimated while the apertures of some short fractures are underestimated. We intend to compare those two methods thoroughly in a separate publication.

## Open Research Section

MATLAB scripts of the far-field stress approximation (FFSA), the ANSYS mesh of the fracture geometry, input and output files of the reference simulation with extended finite volume method (XFVM), and prior and posterior ensembles of the data assimilation framework based on the ensemble smoother with multiple data assimilation (ESMDA) are available at ETH Zurich via <https://doi.org/10.3929/ethz-b-000632502> (Liem et al., 2023).

**Figure A2.** Results with XFVM (a) and FFSA (b) for the same underlying model parameters. Line thickness corresponds to aperture width and line colour to  $\log_{10}$  of the fracture permeability.
